As regards the distribution among foodstuffs, especially those suitable for the rationing of armies, of the substances required for the prevention of beriberi and scurvy, they found that in the preparation of extracts there was always a large amount of loss in the active principle; for example, 10 grams of dried peas was curative in beriberi or scurvy, whereas it took an extract of 40 grams to give the same result. They showed that the anti-beriberi vitamine is very widely spread, being present in a greater or lesser degree in almost every natural foodstuff, but that the principal source is found in the seeds of plants and the eggs of animals. They demonstrated that the vitamine is fairly resistant to heat, and that it is most abundant in the germ of the cereals.

An interesting object lesson was given by the conditions of the British troops during the siege of

*Pyrogenic Therapy, with Remarks on Colloidal Metals. By A. G. Auld, MD. *Brit. Med. Jour.*, Feb. 16, 1916.

Kut. In the early stage, beriberi occurred among the British troops, but it then disappeared. During the first two months they received a ration of wheat flour, but after that from one-third to one-half of the flour was replaced by barley flour and coarse milled wheat flour. These men were also protected from scurvy by receiving an ample ration of horse meat. On the other hand, the Indian soldiers were supplied with cereals and beans, containing an abundance of anti-beriberi vitamins; these had no antiscorbutic properties, and as they did not eat meat, and fresh fruit and vegetables were not procurable, scurvy was very prevalent among them. The deduction was therefore drawn: For the prevention of beriberi it is in the highest degree desirable that the germ and the bran of the wheat should not be excluded from the flour destined for manufacture of bread and biscuit for troops on active service. This is the more necessary when the troops are separated from fresh-food supplies and the rest of the ration consists largely of canned foods, seeing that these articles are deficient in all vitamins owing to their previous sterilization at high temperature. To prevent scurvy, if a supply of fresh fruit or vegetables is not procurable, germinating pulses should be added to the diet.

CANCER IN PORTO RICO.

PORTO RICO is a geographically small, homogeneous community with good vital statistics, and a study of cancer as affecting its inhabitants should be of interest. From figures published by del Toro in the *Boletín de la Asociación Médica* for March it does not appear that the malady is on the increase, although the death rate was above the average during 1914-16. For 1916-17 it agrees quite closely with the figures for 1912-14, being around 1.13, while in 1914-16 the average was 1.345. The figures for San Juan show a similar variation. The average for the five years for the city is 2.45 cancer deaths in one month. No figures are given before 1912, but the author states that the death rate has increased in the past twenty years. Of 141 cancer deaths in San Juan in the past five years, 77, or over one half, the disease was seated in the uterus and breast (59 in the uterus alone). In only one other locality, the penis, were two figures reached (10 cases). There were but 5 cases of gastric localization and but 2 of the bowel. In contrast with these low figures we see 8 cases of cancer of the liver and 7 of the tongue. Of 141 cases but 17 were subjected to the knife in the strictly operable stage, while 84 interventions were practised at an advanced stage. Twenty-six hospital cases of sarcoma are not enumerated under cancer.

If this small material were to be studied by a statistician not familiar with the great variability of cancer, he would doubtless be impressed with the fact that in 91 of 141 cases a sexual organ was the seat of the disease (including scattered cases of the vulva, prostate and testicle), and might hastily conclude that cancer was largely a malady

of such organs—a conclusion which would be controverted by statistics of other countries, Scandinavia, for example, where one could well regard it as a malady of the digestive organs. Next to the 91 cases in sexual parts come 31 cases in which some locality in the head or neck was the site of the disease. These could be explained by the inevitable contingent of epithelioma about the head and face and in the buccal cavity and throat. The digestive organs, with the exception of the liver, show a relative immunity, and there is not a single case of cancer of the colon.

In a second article on cancer in the same journal by Aviles, attention is called to the fact that in 1916 and 1917 one cancer death occurred daily in Porto Rico. The author contrasts this with the calculation that in the United States a cancer death occurs every six minutes. The ratio is 240 to 1, while the population ratio of the two countries is somewhat over 100 to 1. In other words the cancer death rate in the island is less than half that of the United States.

NECROPHAGIC INSECTS.

THAT certain insects at times feed on the dead human body, and may even prey upon it before death, is known to medical jurists even in temperate climates because the resulting disfigurement has caused suspicion of foul play. The chief offenders in this respect have been ants. That such happenings may occur with much greater frequency in hot climates is borne out by an article from the pen of Freire of Bahia (*Brazil-Médico*, January 5) on necrophagic ants. In the Nina Rodrigues Institute in that city it is not uncommon to see in cadavers, including those of stillborn and abandoned infants, lesions of the lips, ears, fingers, etc., due to some species of ant. There appears to be a species of the latter, the *Camponotus abdominalis*, subspecies *atriceps*, which merits the distinction of necrophagic and which conceivably can in sufficient numbers destroy an entire cadaver so far as its soft tissues are concerned. They may be found in association with cadaveric flies, but when present in sufficient numbers can destroy the small cadavers of newly-born children in a surprisingly short time, leaving only the bony and cartilaginous structures. The voracity displayed by these insects is incredible. Unlike cadaveric flies, moreover, the ants prefer a recent cadaver and do not molest one which is in full putrefaction—at least this is true of the *Camponotus*. A comprehensive survey of the ants in the vicinity of Bahia shows that species from other genera are also necrophagic, a large number being described.

News of the Week.

Conservation of Sugar, Glycerin, and Alcohol in Medicines.—Because of the discussion throughout medical and pharmaceutical circles relative to the need of conserving alcohol, glycerin, and sugar, as applied to medicinal products the governmental and other authorities have met and debated the advisability and necessity of conservation measures

from the standpoint of medical needs. As a result of this conference it was deemed advisable to refrain at this time from recommending conservation of sugar and alcohol in so far as their use in pharmaceutical preparations is concerned. The amount of glycerin used in medicine when compared to the available supply was found to be relatively large, and a committee was appointed to investigate formulae, manufacturing processes, etc., requiring glycerin, and to submit plans for the curtailment of the quantity now used in case future developments should make it necessary to adopt conservation measures in relation to medicines.

The American Red Cross has allotted \$25,000 to the Henry Street Settlement for the purpose of speeding up the training of public health nurses needed here and for reconstruction work in France. The course will be open to three-year undergraduate nurses and the term will be from June 1 to September 30.

German Hospital Changes Name.—The directors of the German Hospital, Jersey City, have unanimously voted to change the name of this institution to the Greenville Hospital.

Classes for Clinic Assistants.—In order to supplement the shortage of nurses a new course for hospital clinic assistants has been begun at Teachers College in co-operation with the Bellevue Hospital Social Service, the Federation for Child Study, and the Peoples Institute. Attention will be directed more particularly to child hygiene, nutrition, and related topics that will prepare students to work in the child clinics and social service departments of hospitals. The course aims to train applicants to be clinical secretaries so that they may not only supplement the nursing service but may be useful in assisting to conserve the time of doctors.

Columbia University Lengthens Medical Course.—A resolution presented by the Faculty of Medicine, providing for the addition of a fifth year to the medical curriculum, has been adopted and will become effective for the class entering in September, 1918. The plan adopted involves a redistribution of the clinical subjects taught during the earlier years of the course so that they will be co-ordinated with the fifth clinical year, which will be conducted under college discipline.

Another Hospital for New York.—A campaign has been launched to secure a fund for the erection of a new building on the site of the People's Hospital at 201 Third Avenue, New York. The need of such a hospital is said to be demonstrated by the marked increase in the number of physical defects among the poor in that locality. The plans proposed call for a ten-story structure with full modern hospital equipment. Of the \$250,000 that is needed \$50,000 has been subscribed.

Civil Service Examinations.—The Civil Service Commission of the State of New York announces an examination for the position of Physical and Mental Diagnostician, open to men or women. Applicants must have had experience in the study and treatment of tuberculosis and special training in abnormal psychology, together with experience in the diagnosis and treatment of nervous and mental diseases, and must also be familiar with institutional methods in dealing with mental defectives and psychopathic children. The position carries a

salary of \$4,000. An examination is also announced to fill the position of Instructor in Hygiene. Applicants for this position must be college graduates licensed to practice medicine in the State of New York and must have had broad experience in lecturing on sanitation and hygiene.

Another Pre-natal Clinic for New York.—The Bowling Green Neighborhood Association announces the opening of a pre-natal clinic in the home of that organization, 45 West Street, Manhattan. Pre-natal care was first made a part of the work of this organization when the New York Milk Committee introduced it in 1914. The work was turned over to the Bowling Green Association last year, so that the opening of this clinic is but a step in the expansion of pre-natal work at this center.

In Honor of Dr. Samuel D. Risley.—A testimonial dinner was given at Philadelphia on May 2 on the occasion of the retirement from hospital practice of Dr. Samuel D. Risley, after forty years of continuous service, and he was presented with a silver loving cup. Dr. G. Oram Ring presided and acted as toastmaster, and the speakers included Dr. E. E. Montgomery, Ex-Governor Edwin S. Stuart, Dr. Charles K. Mills, Dr. Howard Forde Hansell, Dr. Peter N. K. Schwenk, Dr. B. Alexander Randall, Dr. William Campbell Posey and Dr. John B. Deaver.

Medical Society Elections.—THE ASSOCIATION OF AMERICAN PHYSICIANS, which met in Atlantic City, N. J., on May 7 and 8, elected the following officers for the ensuing year: *President*, Dr. Alexander McPhedran of Toronto; *Vice-President*, Dr. Herman M. Biggs of New York; *Secretary*, Dr. Thomas McCrae of Philadelphia; *Treasurer*, Dr. J. A. Capps of Chicago; *Councillors*, Dr. Theobald Smith of Princeton and Dr. C. F. Martin of Montreal.

THE AMERICAN SOCIETY FOR CLINICAL INVESTIGATION at its annual meeting in Atlantic City, N. J., on May 5 and 6 elected the following officers: *President*, Dr. H. A. Christian of Boston; *Vice-President*, G. Canby Robinson of St. Louis; *Treasurer*, Dr. Alfred F. Hess of New York; *Secretary*, Dr. Walter W. Palmer of New York; *Councillor*, Dr. George Blumer of New Haven.

THE STATE HOMEOPATHIC SOCIETY and the ECLECTIC STATE MEDICAL SOCIETY OF SOUTH DAKOTA, at their joint meeting held in Sioux Falls on April 24, elected the following officers: *President*, Dr. J. W. Elis of Elk Point; *Vice-President*, Dr. C. Clark of Woonsocket; *Secretary and Treasurer*, Dr. E. W. Fiege of Huron.

THE MASSACHUSETTS SOCIETY OF EXAMINING PHYSICIANS, at its annual meeting held in Boston on April 27, elected the following officers: *President*, Dr. Frank J. Schubmahl; *Vice-Presidents*, Dr. H. H. Howard, Dr. C. S. Benson and Dr. John E. McCartin; *Secretary*, Dr. J. H. Stevens; *Treasurer*, Dr. John Phelps.

Maternity Center Opened.—The Women's City Club of New York, which is co-operating in the work of Baby Year, has opened a maternity center at 218 East 74th Street. The work of the center includes the securing of expert treatment for those who develop symptoms of abnormalities and aiding mothers and babies who need special care. Mothers are shown the proper outfits for babies and how to make the necessary clothing from ma-

terial supplied to them at cost. The committee is working on plans for supplying proper food to expectant mothers at cost.

Public Health Service Combating Pellagra.—The United States Public Health Service is making an effort to reduce the prevalence of pellagra in certain sections of the country and thereby increase the efficiency of labor at this crucial time. According to estimates made by the Public Health Service there are 125,000 persons who had this disease last year and of these more than 6,000 died. The campaign will consist in educational propaganda teaching that the disease may be prevented by a well-balanced diet, including sufficient quantities of milk, lean meat, beans, peas, and green vegetables. The literature of the Public Health Service contains bills of fare which are recommended to prevent or cure the disease.

Death Rate from Tuberculosis in the Principal Cities of the United States.—According to a bulletin published by the Health Department of Chicago, among the ten principal cities of the United States Pittsburgh has the lowest death rate from tuberculosis, for the year 1917, the rate being 147.05 per 100,000 population. Chicago is a close second with a rate of 148.67 per 100,000. The rates of other cities in this group are: Detroit, 160.66; Boston, 170.87; Cleveland, 174.7; New York, 176.75; Philadelphia, 194.81; Los Angeles, 199.42; St. Louis, 202.95, and Baltimore, 236.61.

Obituary Notes.—Dr. ISAAC ADLER of New York died at his home in this city on May 4, aged 69 years. He was born in Alzey, Germany, in 1849, and was a graduate of Heidelberg in 1871. He had been Professor of Clinical Pathology at the New York Polyclinic Medical School and consulting physician to the Polyclinic, German, and Beth Israel Hospitals, and to the Montefiore Home. Dr. Adler was a member of the American Medical Association, the Association of American Physicians, the American Pathological and Bacteriological Society, the American Society for Clinical Investigation, the Gastroenterological Association, and the New York Academy of Medicine.

Dr. CHARLES ORVILLE BECHTOL, a graduate of the University of Illinois College of Medicine, in 1901, died at his home in Marion, Ohio, on April 21, aged 44 years.

Dr. WILLIAM HENRY HARRISON VARNEY of Charlotte, a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1862, died at a hospital in Burlington on April 22, aged 78 years. Dr. Varney practised medicine in Vermont for fifty-five years and served as representative from Charlotte to the State Legislature in 1888. He also served as health officer of Charlotte, and was a member of the board of pension examiners.

Dr. JAMES RUNDLETT MAY, a graduate of Jefferson Medical College, in 1866, died at his home in Portsmouth, on April 22, aged 77 years. He was an assistant surgeon in the Civil War and later served on the Board of Pension Examiners. Dr. May was Director of the New Hampshire Society for the Prevention of Cruelty to Animals.

Dr. JOHN N. HELMKE, a graduate of the University of Louisville, Medical Department, in 1875, and a surgeon during the Civil War, died of bronchopneumonia, on April 19, aged 83 years.

Dr. PAUL NATHAN LITCHFIELD died at Camden, N. J., on May 1 at the age of 44 years. He was graduated from Jefferson Medical College in the class of 1895. He was a member of the New Jersey House of Assembly and he was connected with the staffs of the Tuberculosis Hospital at Ancona, N. J., and with the County Hospital at Blackmoor, N. J.

Dr. AUBREY J. RICHARDSON, formerly of Philadelphia, died at Pasadena, Calif., on May 4 at the age of 59 years. He was graduated from Hahnemann Medical College and Hospital of Pennsylvania in the class of 1882.

SURGEON WILLIAM H. RUSH, U. S. N. Lieutenant Commander, retired, died recently at Ardmore, Pa., at the age of 66 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1873. He was for many years surgeon of the old training ship, "Saratoga." He was commissioned assistant surgeon in the Navy in 1877. Three years later he became a passed assistant surgeon and in 1894 surgeon.

Dr. HENRY MERRIMAN WILSON died at his home in Baltimore on May 8 at the age of 90 years. He was graduated from the University of Maryland Medical Department in 1850 and for many years was president of the medical faculty of that institution. He was also a former president of the Gynecological Society of Baltimore.

Dr. EPHRAIM MORRISON, a graduate of Bellevue Hospital Medical College in 1875, died at his home in Newton, N. J., at the age of 66 years.

Dr. GEORGE W. BLISS of Valley Springs, So. Dak., died of pneumonia in a local hospital on April 29, aged 50 years. He was a graduate of the College of Physicians and Surgeons, Minneapolis, in 1895.

THE RED CROSS AND ANIMAL RESEARCH WORK; A PROTEST BY THE BUFFALO ACADEMY OF MEDICINE.

A SPECIAL meeting of the Buffalo Academy of Medicine was called on April 24 to consider the recent action of the American Red Cross in revoking its decision to appropriate money for animal research work, and allowing individual generosity to refund that already expended and also to supply funds for the continuance of the work. The attention of the Buffalo Academy of Medicine was called to this matter by a statement for publication issued by Harvey D. Gibson, general manager of the American Red Cross in Washington, which statement appeared in the *New York Times* on April 11, 1918. Mr. Gibson explained briefly why the Red Cross first decided to undertake animal experimentation which was done "upon the recommendation of army medical officers and a number of eminent scientists in this country." He also stated that prompt action was necessary; that the use of money in this way was proper from the Red Cross point of view, because it would be difficult to imagine any more important duty upon the Red Cross than to seek for any means of prevention and remedy for sickness among soldiers." He further stated that "the Red

Cross does not believe it should take action either for or against animal experimentation."

After a careful consideration and thorough discussion of this action of the American Red Cross, the Buffalo Academy of Medicine by unanimous vote appointed and instructed a committee to prepare a strong protest against what it believes to be an ill-advised procedure, which is contrary to the policy adopted by the military authorities. If the original decision of the Red Cross to appropriate money for animal research was wise, the reasons for its change of policy are weak and unconvincing. The committee submits the following report, which it has been directed to transmit to the American Red Cross, the local Red Cross, and to the medical journals and public press.

It is with regret, deeply tinged with indignation that the Fellows of the Buffalo Academy of Medicine learn of the recent decision of the American Red Cross to withdraw appropriations of money for animal experimentation in its medical and surgical work at home and abroad.

To animal research work the world owes almost innumerable important discoveries. What would be our unfortunate and helpless position to-day without diphtheria antitoxin, antimenigitis serum, antitetanic serum, vaccination against typhoid, without the Wassermann test and salvarsan? The value of these has long since passed the experimental stage. Not a single dose of these remedies can be standardized without tests upon animals. In the domain of surgery who can estimate what animal research work has added to the successful results of the surgeon in aseptic and antiseptic surgery, bone grafting, the surgery of arteries, nerves, joints, intestines, and, in fact, all branches of operative repair? Even the diseases of animals have been equally lessened by knowledge gained through experimental research. Is it generally appreciated that every sterile dressing, the simple first application of iodine, even the cleansing of the hands and much of the simplest work of the surgeon and nurse owe their origin to biological research?

We have not yet by logical reasoning reached the conclusion that the life or temporary illness of a guinea pig, mouse, or any animal can be considered when the life of man is at stake. Has the welfare of the lower animal attained special importance just now, when millions of men are offering the supreme sacrifice in a foreign land? Animal experimentation and biological research have never been so vitally necessary as in the present war. The demand to-day is imperative to save every life possible, which is endangered by the horrible methods of a barbarous foe. In every properly conducted modern laboratory animal suffering is minimized to the last degree, not only from humane motives but to obtain more accurate scientific results. The benefits are immeasurable, while pain is absent or infinitesimal.

It is impossible to estimate how seriously interference with animal experimentation will affect the safety of our soldiers and sailors. It will make impossible the conquest of several terrible diseases likely to become prevalent in our army, and which may later spread to our civil population.

Scientific investigation is now particularly directed toward lessening the ravages from pneumonia, gas-gangrene, and trench fever. There are hopeful signs that this will be accomplished in the near future, if not prevented by ignorant and vicious interference. We agree with the *New York Times* that "Red Cross money, in the amount that was proposed, could not possibly have been better invested than in the establishment of a biological laboratory near the scene of war, for the study of the maladies of soldiers, which this sort of research work has not yet conquered."

As American citizens we are opposed to making this vital work dependent upon the beneficence of any individual, or to the Red Cross delegating or dismissing the matter by leaving it to the generosity of any person or group. The money is given the Red Cross to prevent and relieve suffering, and save lives. It is a distinctly national duty in every way, due to those who offer their lives for their country and should be met squarely and not dodged or evaded. We regret that the American Red Cross officials yielded to the threats of the antivivisectionists and like propagandists.

We ask assurance that provision be made for adequate experimental laboratory work. It is distinctly the function and duty of the Government to supply this need through a national agency such as the Red Cross or the War Department.

The American Red Cross by its decision made in weak compliance with the threat of an intolerant minority of its provisional supporters has established a precedent which may prove calamitous and far reaching in sinister consequences. Other irrational demands will follow and additional attempts to render scientific advance impotent will be aimed at our Army, Navy and public Health Service. Already seditious advice has been published, plainly designed to discourage enlistment and to obstruct the draft, by false and malicious statements concerning vaccination for the prevention of various diseases in the Army. This advice is fully as vicious as any promulgated by the German propagandists. The Red Cross by its action has taken a long step backward and failed to render deserved recognition of medical science.

The medical profession has been very patient and silent under the load of malignant abuse and false accusation, but growing resentment and an increasing determination to resist the intolerable fettering influences, forced upon it by perverted or delusional doctrines must lead to stern resistance. The time has come for us to protest against national submission to ignorance and fanatical prejudice, and we appeal for scientific progress, and for the return to common sense. The physicians and surgeons of America do a large proportion of the active, effective work of the Red Cross, and therefore we feel justified in stating our position.

We recognize and appreciate fully the splendid and tremendously efficient work of the American Red Cross. We realize that the sacred obligation to loyally support the Red Cross rests upon each and every citizen of the United States. We pledge our continued, devoted support to the Red Cross. We will not attempt to coerce the American Red Cross by the threat of discontinuance of personal and

financial aid, as did the opponents of this measure, which action we regard as most unpatriotic.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE MEDICAL CERTIFICATION OF RECRUITS—THE COMING MINISTRY OF HEALTH—THE ADJUSTMENT OF DIET—DEATH OF MR. GUY ELLISTON.

LONDON, April 18, 1918.

WITH the large extension of the military age, namely, from 41 to 51, and in the case of medical men to 55, the medical certificates in connection with the men appearing before the National Service Medical Boards will have to be very carefully given. Frequently medical certificates purport to prejudge a man's fitness or unfitness for military service, though written with absolute sincerity by the medical practitioner. The authorities at the National Service headquarters acknowledge that a well-drawn certificate from a private practitioner may be of great assistance to any recruiting board, and they say, though not to a very convinced audience, that such certificates receive full consideration before the boards come to their decisions on the cases in question; but what the private practitioner has to remember is that many men, holding that their work in a civil capacity is at the present time more valuable to the conduct of the war than anything which they can conceivably learn to do after enlistment at this late date, will try to evade military duty. The responsibility of medical men for the absolute accuracy of their certificates must in such cases be deeply realized, and the Minister of National Service has issued a circular notice to this effect during the present week, quoting the penal powers which may be exercised by the General Medical Council against practitioners who certify loosely. There is no doubt that these powers will be used where necessary.

Despite the fact that the political program appears already overfull, and that the position of military affairs on the English front is at this date of writing in a confessedly critical condition, rumor again has it that a bill may be brought into the House of Commons to set up a Ministry of Health, and to coordinate under one roof and one cabinet minister all the functions now discharged by the medical branches of half a dozen different government departments. Principal among these departments are the Local Government Board of the State authority for preventive medicine, and the Fraternal Insurance Commission as the State authority for the clinical care of from 12 to 14 millions of the population. The free discussion held by the fellows of the Royal Society of Medicine on April 15 to consider the position of the medical profession of the country under such a grand departure, though initiated by the opener as an academic de-

bate, had behind it a practical purpose. That purpose was to stir the medical profession to consider their position and to be ready to take concerted action in the direction best needed for the maintenance of the health of the country when the new legislation came actually upon the tapis. It is certain that any measure of national health must be in full accord with the best scientific opinion if any real satisfaction for the country is to be derived from its operation; and it is necessary that the medicine of the country should be ready with that opinion at the proper time, and not be found differing over details and thus frittering away its influence. The debate was opened by Surgeon-Major Gordon Dill, a distinguished provincial physician, senior on the staff of the Sussex County Hospital, which has been the center of strenuous war work at Brighton, who presented a scheme which fused under one head, to be a minister of cabinet rank, the preventive and clinical medical practice of the country. The minister was to have four assistants-in-chief (one each for England, Ireland, Scotland, and Wales), each of whom was to have a chief of executive for (a) preventive and (b) clinical practice. Under the first would fall all the existing activities of the Local Government Board and the Board of Education, and under the second the work now done by the voluntary hospitals, the poor-law infirmaries, and the panel practitioners. The energies of both sections were to be combined at the periphery, institutional treatment and laboratory facilities being common. Under such a scheme Major Dill claimed that all existing interests would be maintained, and a proper future assured both for the thousands of practitioners who have now left their private work for years to assist the medical service of the army and navy, and for the oncoming students who might be expected to join, not only in good quantity but in fine quality, a service of such promise. The scheme was blessed in the debate by Sir Arthur Newsholme, principal medical officer of the Local Government Board, who spoke with great official caution, but who testified with unchallengeable figures to the progressive work of his department; and Surgeon-General Sir Bertrand Dawson, a powerful member of the Army Advisory Medical Council, who sketched the future of medical practice, when all the practitioners of a locality had at their disposal a properly equipped hospital, with annexes for every specialty and a good laboratory, the buildings to be found and kept up by the State. The scheme was avowedly a *ballon d'essai*, put forward to excite interest and challenge amendments, and as such may prove a valuable nucleus for future communications. Sir Arthur Newsholme's speech made it fairly clear that the wisest course for new legislation to take would be to constitute any new department a branch of the Local Government Board, which has under its hands already the charge of so many important medical interests. And when the new department grows too big for the parent nest it will be time enough for it to start on an independent career.

The Royal Society has issued a wide, and what may be a quite useful invitation to naturalists, chemists, botanists, and all practical observers, to send in suggestions for the utilization as food of material hitherto unemployed in the British diet.

There is no doubt that the committee receiving the varied suggestions will soon have their desk loaded with impossible ideas and cranky formulæ and recipes, but among the dross there should be ore. To begin with, the fresh-water fish of the British Isles is almost uneaten, but in bulk it counts for a good deal, and some of it is quite good, and the experience of certain inland lake localities will here be very useful. Botanists know of many substitutes for green vegetables which grow wild in wood and hedgerow, and although a promising season for regular vegetables approaches, it will be sound economy to investigate the claims of anything that might supplement them. But to chemistry the mind naturally turns as the science of all others that may here be useful, for the production of synthetic food is in its infancy. Simultaneously with the invitation of the Royal Society there has been published by the Medical Research Committee a most valuable report upon the diet of the munition workers, prepared by Captain M. Greenwood, a well-known statistician, and Lord Dunluce. The conclusions of the report are based on data collected during the early part of last year, for the most part, in the canteens and hostels serving the munition factories, and its principal message is that in the immediate future we must look to carbohydrates as the chief provision of energy for work to be done. A radical reduction of fats will be necessary, in view of the short supply of meat and fat-supplying commodities, but the observers assure us that the energy to be derived from potatoes and cereals can be safely substituted. They give in support of their views a determination of the proportions of the various ingredients of a diet, and the number of calories needed to maintain life under conditions of varying stress, the whole forming a highly practical document, which should be of great use to the community at the present time, if its lessons are acted upon by those in authority.

The medical profession of the country, a not too well organized body, has suffered a severe loss on its business side by the sudden death of Mr. Guy Elliston, for just upon twenty years financial secretary and business manager of the British Medical Association. Elliston, who was trained with a big steamship company in commercial methods, and who learned the managerial side of journalism at the office of the *Naval and Military Magazine* and the *Public Health Magazine*, took over the financial management of the British Medical Association exactly as that body was undergoing thorough reconstitution. Reconstitution, for purposes of expansion, as well as of reform, is apt to be a very costly affair, and the association, which was rich when it started on what was practically a new career, spent its resources royally, but also quite judiciously. Large liabilities were, it is true, incurred, but a large increase in income and in stability of position was secured, and, much owing to Elliston's acumen and devotion, the association would soon have been out of debt, when, and only some nine years after the rebuilding of the premises and the entrance upon heavy commitments, Mr. Lloyd George introduced the National Insurance measure. This measure convulsed the medical profession and threw a grave strain upon the finances of the association; but Elliston's conduct of affairs again

brought the concern through well, though not to enjoy for long freedom from monetary cares. For three years after the introduction of national insurance came the outbreak of the great war, and Elliston from the beginning had to face difficulties which steadily increased as time went on, in connection with the issue of the *British Medical Journal*, whose revenue, looked at in one way, is the main source of income of the association. He worked unsparingly and successfully in circumstances of the greatest difficulty, and it is more than likely that his rapid succumbing to an attack of pneumonia was due to the fact that, always a delicate man, he had overtaxed his strength. Elliston was a younger son of the late Dr. William Elliston of Ipswich, and was 48 years of age. His father had been president of the British Medical Association.

OUR LETTER FROM PARIS.

REST AND CONVALESCENT CENTERS—SAVING THOSE WHO CANNOT SAVE THEMSELVES.

PARIS, March 25, 1918.

GENERAL PERSHING having some time since prohibited Paris as a leave center for the soldiers, other appropriate points had to be selected, and among them the Medical Authorities selected Aix-les-Bains and the Savoie region. The opening of the American Army rest camps in the Savoie region occurred on February 25, the first contingent of Uncle Sam's fighting men is expected to arrive this afternoon, or at the latest tomorrow. Hotels are ready to receive them, and the army has provided for everything that will make the men comfortable and feel at home. By next Wednesday there will be some three thousand troops enjoying the pleasures and wonderful climate of middle France.

Before some forty directors of various Red Cross activities yesterday afternoon, Mr. Edward Eyre Hunt, chief of the Bureau of Reconstruction and Relief and formerly delegate of the Commission of Relief in Belgium for the province of Antwerp, and Dr. Edward T. Devine, chief of the Bureau of refugees, described Red Cross work in the field as observed by them on recent inspection trips. The meeting was held in the office of Mr. Homer Folks, director of the Department of Civil Affairs.

Mr. Hunt spoke enthusiastically of the work in the liberated regions, where the effort of his Bureau is concentrated on increasing the agricultural production and thus releasing shipping from America for munitions rather than food. "Every brick means ounces of bread," he said.

Dr. Devine described the work for Refugees in the provincial department.

These are the elements of our problem: communities already full to the point of saturation, lodgings scarce or non-existent, food and fuel equally scarce, the residents naturally hospitable, but sorely tried by previous experiences; refugees weary, worn, grief-stricken, glad to be repatriated, wondering what fate may have in store for them next, discouraged, pathetically receptive.

Into this situation comes the fresh, vigorous, carefully-instructed, enthusiastic, eager Red Cross delegate; a credit of 5,000 fr. in the bank, with more to follow if it can be wisely used; supplies in the Paris warehouses ready to be sent if the embargo

permits; officials a little puzzled at first, but ready to accept our assistance, and ordinarily keen about it after the first or second interview. We are taking it for granted that the lodging, ordinary food, and the greater part of the clothing required will be supplied by the Government, in so far as the families cannot supply these things for themselves; that our task is to make the homes hospitable, sanitary, even if we can, comfortable. In other words, that we are to install the families in their foyer, to make them feel "chez eux" in the midst of themselves, so to speak. We are supplying clothing, fuel, even in some cases tools, chickens, materials with which to work; but our long suit is furniture—beds, tables, chairs, stoves, buffets, mattresses, bolsters, and blankets. Five hundred francs we are spending when necessary on the family, 100,000 fr. for a convoy of 600 people. Every day a convoy like this is arriving somewhere in France; every day our delegate is there to meet it.

It is a necessary task; it is meeting a war problem; it is helping the victims of the war; it is preventing this increment of the population from adding to the disaffected, unjustly treated elements of the population, and transforming them, to some extent, into hopeful and productive families. It is removing obstacles from before their feet at the moment of their entry into their home country; it is holding out to them hands of sympathy, of encouragement, of brotherhood; it is an expression of a Franco-American alliance; it is an expression of American generosity in war time, a legitimate expression of Red Cross sentiment, of the spirit of humanity and justice and democracy, for which, in this war, America and her allies, France and her allies are jointly battling.

Miss Margaret Curtis of Boston, who is arranging to repair and complete Paris buildings hitherto unoccupied, making them available as lodging for refugees, and Mme. Eduard Fuster, of Dr. Devine's bureau, also told of their work.

6. Primary Syphilis of the Eyelid, with Report of a Case. Henry D. Lloyd.

4. A Study of Diphtheria Carriers.—D. M. Lewis points out that measles is often followed by diphtheria and refers to results previously obtained by him from a consideration of this factor and reported in the *Interstate Medical Journal* (Vol. XXIX, No. 9). He also gives the results of an investigation conducted into the prevalence of carriers, the majority of whom he believes to be nasal. In October and November of 1917 an increasing number of cases of diphtheria were reported in New Haven. Lewis therefore engaged two nurses to make a survey of all those of school age and also, in districts where cases had occurred, of those not of school age, with a view to finding carriers of the disease. Cultures to the number of 687 were made and 23 carriers not of school age and 34 of school age were discovered, i. e. approximately 2 per cent. of the school

population were found to be carriers. In the case of such carriers the author recommends the following treatment: Constant inhalation by means of dropper, nasal swab or atomizer every hour in a 1 per cent. solution of gum camphor and eucalyptol in mineral oil for all individuals over five years of age, and a one-half per cent. solution in the case of younger individuals. He attributes the efficacy of this treatment partly to its hourly use as contrasted with the frequent practice of using antiseptics only once or twice a day. *Results:* Lewis points out that during the severe epidemic of diphtheria that occurred in 1906, there were 35 deaths in 5 months, and 9 more during the first three months of 1907. The next severe epidemic was the one in 1917, when during a similar period there were only 8 deaths, although during the early part of the period the frequency of cases was as alarming as at the beginning of the 1906 epidemic. During the first three months of 1918, 5 deaths occurred; that is, during the eight months of 1917-18 there were 13 deaths as against 44 during the same period in 1906-07. Such positive results produced by two months' work, he says, bespeak the rationality of the continuous operation of detectives for finding carriers. In summarizing the results of his work, Lewis says: (1) The continuous search for carriers in controlling diphtheria is an exact sanitary measure of prevention. (2) All individuals with acute catarrhal nasal conditions are potential acute nasal diphtheria carriers; it requires the presence of a chronic carrier, generally also nasal in type. The permanency of the former when made a carrier is dependent on the degree of nasal obstruction. (3) All individuals convalescent from any respiratory disease, however mild, constitute the largest proportion of nasal carriers of diphtheria. Investigation of all such individuals and their isolation, if carriers, is the essential basis of control of diphtheria. (4) In general, cases follow the production of acute nasal carriers by chronic ones. (5) Responsibility for any frequency of the disease is solely that of health authorities.

7. Hydronephrosis as an Underlying Cause in Attacks of Acute Abdominal Pain.—Sergeant Price Martin lays emphasis upon the importance of bearing in mind the possibility of a hydronephrosis as an underlying cause in doubtful cases of attacks of acute abdominal pain. He points out that in cases of hydronephrosis due to constant mechanical obstruction to the ureter, a complete uranalysis as a rule reveals no pathological findings and an x-ray examination of the kidney and ureter will also generally prove negative. The kidney is then frequently excluded in the diagnosis and the patient operated upon for appendicitis. An appendectomy is performed and, the pain still persisting, a second operation is done for the removal of the gallbladder or, in the case of a woman, an ovary. Still no relief is obtained and the patient is treated for neurosis, lumbago, ptosis, indigestion, and so forth. In a case of this nature, a urological examination, including a complete uranalysis of a twelve or twenty-four-hour specimen, and an x-ray examination of the entire genitourinary tract should be made to determine whether a calculus is lodged in the kidney or ureter on either side, though subjective symptoms may be present only on one side. Should the plates prove negative, a cystoscopic examination should be made with the catheterization of both ureters. As a rule, the demonstration of obstruction to the ureteral catheter in the upper ureter and the existence of residual urine beyond the obstruction, which is characterized by its rapid flow, will suffice to call attention to the probable existence of

hydronephrosis. Should any doubt arise, the condition may be demonstrated by the overdistention method, but the question may then arise as to whether a pelvis that will only hold from fifteen to twenty-five c.c. is dilated to two or three times its normal capacity or is an unusually large pelvis. In order, therefore, to determine the exact condition present, the outline of a well distended pelvis as seen in a pyelogram may prove of more definite diagnostic value than any other data. The first deviation from normal is a flattening of the terminal irregularities seen in the normal minor calyces, while the more advanced cases vary from a mere flattening of the apices of the major calyces to the complete diffusion of the calyces and pelvis into a diffuse outline of a rounded sac. Martin goes on to describe the pathological and histological changes that take place in the kidney and gives diagrams of normal and dilated pelves, some of them from a collection of pyelograms made at the Mayo Clinic. He urges upon the general practitioner the advisability of consulting with a competent urologist in all doubtful cases of acute abdominal pain before subjecting a patient to unnecessary operations.

3. Are All the Tubercle Bacilli Found in the Sputum Virulent?—H. J. Corper gives the results of an investigation undertaken to determine the range of virulence of tubercle bacilli isolated from the sputum in open cases of pulmonary tuberculosis. He found that in the majority of such cases the tubercle bacilli which could be isolated on artificial mediums from the sputum were virulent enough to produce systemic tuberculosis in guinea pigs, by means of doses as small as 0.000,001 mg., and that the range of virulence was very small; this latter observation was also made by Gilbert and Gregg, who found it to lie between 10 and 120 bacilli. Corper points out that if the virulence of the bacilli as cultivated on artificial mediums is a direct expression of their virulence in the sputum, there is only one conclusion to be drawn from these findings, and that is that in open cases of pulmonary tuberculosis the tubercle bacilli discharged by droplet or by expectoration, while still uninfluenced by drying and light, are a danger to mankind through direct transmission at least. He points out that Webb and Gilbert found that a culture of human tubercle bacilli, sufficiently virulent to infect a guinea pig when ten bacilli were used, was also capable of infecting a child in practically the same dose, and that it seems justifiable, therefore, to conclude that the tubercle bacilli found in the sputum of patients in open cases of pulmonary tuberculosis (provided the bacilli capable of artificial cultivation are a true index of those existing in the native sputum) vary only slightly in virulence for guinea pigs, and are for practical purposes nearly all pathogenic. That is, as may be deduced from Gilbert and Webb's observations, in 97 per cent of cases they will infect a child in a dose of less than one-millionth milligram. Corper adds that these experiments also seem to lay special emphasis on the importance of examination of the sputum of men in the military service or about to enter it.

3. A Study of the Cardiac Disabilities of Soldiers in France (V.D.H. and D.A.H.).—Colonel W. E. Hume gives the results of an inquiry in the cardiac and circulatory conditions of 5000 soldiers sent to a base with a diagnosis of V.D.H. and D.A.H. He found that the symptoms of shortness of breath, pain in the region of the heart, palpitation, and giddiness occurred under varying states of body and mind, and in the majority of cases was unable to assign a definite pathological basis. These cases may be divided into those who throughout life have been unable to undergo physical exertion of any kind, possibly because of an inherent difference in the potentiality of the heart muscle; those who owe their disability to permanent or temporary damage to the heart muscle; and neurasthenics or those suffering from shell shock, in whom the fault lies in the nervous innervation of the heart rather than in the heart muscle. Cases of type I may improve to some extent under careful and graduated training but the majority are never fit for great and prolonged physical exertion. In the second group are included cases in which there is a definite history of rheumatic fever—in the present series 10.8 per cent. and in the ease of other observers 20 per cent.—and those convalescent from infectious diseases such as the enteric group of fevers, influenza, and trench fever. A study of onsets of symptoms with a view to their relation to prognosis produced no definite results. Hume found that 56.4 per cent. of cases occurred between the ages of 20 and 30, but of course the majority of the men serving in France were of this age. In classifying the civil occupations of the cases, he found that the lighter classes of occupation provided the largest number of patients. In the various branches of the service he found that the Infantry and labor companies afforded a higher percentage of D.A.H. cases than of ordinary medical cases. Hume points out that the rationale of treatment is the same in all cases, the most important factor being the abolition from the patient's mind of the idea that he has a diseased heart. This, with good food, undisturbed sleep, occupation and outdoor exercise, regulated and under discipline, is all that is necessary. By this method, he states, 50-60 per cent. can be sent back to their original work after 4-5 weeks. The remaining 40-50 per cent. are unable by reason of poor physique, actual disease, or age, to undertake any kind of work or hardship. Apart from those who suffer from actual heart disease or some other organic disease, he considers that nearly all are fit for some service in France. He adds that it would be of great advantage to the individual and to the Army if those who are considered to be unfit for general service could be allotted the work for which they are mentally and physically fitted.

3. The Importance of Regulating the Fat-intake in Diabetes Mellitus.—P. J. Cammidge points out that in the treatment of diabetes mellitus control of the fat allowance is quite as important as regulation of the carbohydrate and protein intakes. Bloor was the first to carry out a systematic study of the fat content of the blood of diabetics. He found that out of thirty-eight

cases a lipid value of the blood in excess of the normal average was present in thirty-six, and in all but three cases it exceeded the highest limit met with in healthy persons. A marked increase, up to 100 per cent. or more of normal values, was found in all severe cases, but as a rule the more severe and long standing the diabetic condition the more marked was the abnormality in the blood lipoids. The evidence at present available suggests that the excessive lipid value of the blood originates in the fat of the food, and is due to the partial failure of the mechanism for dealing with fat arising from the essential nature of the diabetic state. Blood found that there was no definite relation between high blood lipoids and the occurrence of acetone bodies in the urine. Moreover, that diabetic lipemia is not due to change in the reaction of the blood is indicated by the fact that the greatest possible reduction in its carbon dioxide capacity by acid poisoning produces no characteristic change in that direction. It would therefore seem that the tendency to imperfect utilization of fat in diabetes is not dependent upon any other feature of the disease, but is a primary phenomenon of the condition. Cammidge points out that it may be taken as a general working rule that fat unbalanced by an adequate available supply of other foods is poison to the diabetic, and that the craving for bread and other starchy foods is an expression of a natural want that should be dealt with by restoring the balance in the diet by reducing the fat rather than by increasing the carbohydrate, as is usually taught. He further points out that from experiments conducted by Allen, it seems reasonable to conclude that the hyperglycemia and glycosuria following excessive feeding with fat are due to a failure of metabolism consequent on the gain in weight above what the defective assimilative functions are able to cope with, and that any attempt to induce a high level of nutrition with fat results in an aggravation of the diabetic condition similar to that which follows a like attempt with carbohydrate or protein, although its effects are slower and more insidious. These observations make it clear that in addition to rendering the urine sugar-free by limiting the carbohydrate intake or adjusting the protein allowance, it is also necessary to ascertain the optimum amount of fat which will meet the needs of patients, prevent acidosis, and avoid the onset of glycosuria. Cammidge has obtained satisfactory results by the fasting treatment; in some cases in which sugar returned he found that an excess of protein was being taken and in others that the fat content of the diet was the difficulty, and when this was adjusted to the patient's metabolic powers the glycosuria promptly ceased and did not return. He states that in treatment the aim must be a steady weight which can be maintained without overtaxing the patient's defective metabolic powers. Gain in weight must be sacrificed to well-being and satisfaction of the appetite to length of days. Individualization of the diet, in which the allowance of carbohydrate, protein, and fat is regulated by the tolerance of the patient for each and by his powers of dealing with the diet as a whole, is the line along which the treatment of diabetics is developing.

5. Medical Aspects of the Food Problem. Robert Hutchison.

5. Medical Aspects of the Food Problem.—Robert Hutchison considers the effect on health of the present food shortage in England under the following headings: (1) Effects of a diminution in the diet as a whole.—He points out that though a reduction in the fat ration of $\frac{1}{2}$ lb. per week would entail a loss of a stone in weight in seven months, this loss is not progressive, the individual being able to maintain a lower weight on the diminished diet. This is due to the lessened output of energy required to transport a smaller body weight and

an economy in "fundamental metabolism." A lesser body surface also means a diminished heat loss. There is, however, a danger point which is probably represented by the point at which the body begins to lose nitrogenous tissue as well as fat, when liability to disease, especially tuberculosis, and the tendency to functional nervous disorders becomes greater. The necessity of maintaining an adequate supply of vitamins makes it important that the diet, if scanty, should be varied in character. (2) Effects of an altered ratio of the chief nutritive constituents (proteins, fats, carbohydrates).—Hutchison shows that the present restrictions tend to make the diet poorer in protein and fat and richer in carbohydrate than under normal conditions. Physiological needs, however, can be met by a much lower protein content than that of a freely chosen diet which is about 100 grams or more. During childhood and adolescence and during pregnancy the protein intake must be maintained at a high level, and therefore extra rations of milk are allowed which should be supplemented by a free use of unrationed nitrogenous foods. The author remarks that it will be interesting to see whether the reduction of meat in the diet will lessen the incidence of such conditions as gout, epilepsy, and migraine. He says it should be beneficial to sufferers from chronic vascular and renal troubles, but will probably increase liability to tuberculosis. Special provision has been made in the rations for diabetics and children with so-called coeliac disease, since of course carbohydrates must be avoided by these patients. (3) Effects of alterations in quality of staple foods.—Bread is the food that has been most altered since the war. Hutchison states that, chemically, war bread is superior to white bread and that experiments have shown that it is well digested in the physiological sense. He thinks that many of the complaints that it is "indigestible" are imaginary, but that it may disagree with old persons with defective teeth and feeble stomachs or with patients suffering with colitis; thorough toasting and careful chewing will get over the difficulty in most cases. Margarine as a substitute for butter, he says, is perhaps deficient in certain vitamins but, if the diet is varied, it is not likely to affect health. It is probable, also, that milk may not be as free from bacteria as formerly and there is some reason to believe that there has been a substantial increase in tuberculosis (especially of the abdominal form) amongst children; this, however, is a matter deserving further attention and inquiry. Reviewing the whole question, Hutchison states that it may be said with confidence that there is no reason to suppose that the food difficulties, so far as they have gone at present, have had any adverse effect on health; if anything, their tendency has been perhaps in the opposite direction.

Berliner klinische Wochenschrift.

February 18, 1918.

Experiments with Friedmann's Antituberculous Vaccination.—Kölliker believes that it is only by the use of Friedmann's vaccination that a cure can be obtained in tuberculous joints or localizations in other viscera, such for example as the testicle or epididymis, with complete return of the functions and without destructive surgical interference. Kölliker advises all medical men to resort to this vaccine as early as possible in the treatment of tuberculous lesions. Kölliker has noted that the arrival into the system of a new antigen (such as antivariolic vaccine) may profoundly disturb a treatment which would otherwise have undergone a favorable evolution. Such enthusiasm is more than suspicious. Remember the death rate resulting from Koch's tuberculin of thirty years ago.

Therapeutic Experiments with Friedmann's Antituberculous Serum.—W. Kühne notes, as does the writer of the above article, the happy effects of this treatment, as compared with other ordinary treatments, medical or surgical, of tuberculosis. It is necessary to follow closely the evolution of the primary vaccination in order to estimate the indications for future intravenous injections. Any deviation from the rules laid down for the administration of the exact (sic) procedure of Friedmann will result in a cessation of the amelioration of the case. The same antagonistic effect

to this treatment will result from an intercurrent infection, such as smallpox vaccination or scarlet fever. The writer records the case histories of all the cases treated so far, to the number of twenty, by Friedmann's procedure. The conclusion offered is that one obtains by this exact treatment by "Friedmann's remedy" such cures of pulmonary and other tuberculoses as no other therapeutic means so far employed have been able to attain.

Cocaine Idiosyncrasy.—E. Tobias and K. Kroner record the case of intolerance for a very small dose of cocaine, characterized by fever and organic nervous and cardiac symptoms, followed later by trophic disturbances of the fingers and disturbances of the equilibrium when standing.

Münchener medizinische Wochenschrift.

February 19, 1918.

The Prognosis and Treatment of Pneumothorax.—Harms has noted that early puncture seems to be decidedly better than incision. In a like manner it would appear that an accord in opinion has been made to attribute cases of sudden death to gas emboli; "pleural eclampsia" has no other mechanism than this. The writer regards high intrathoracic pressure as bad; likewise an endeavor to break down adhesions may lead to complications, such as infection of the bronchi in the opposite lung, excessive compression of the heart, laceration of the mediastinum, emphysema, etc. As to pleural exudates which may arise during treatment, no fear need be entertained, only their purulent transformation is a distinctly unfavorable sign. The procedure cannot be controlled by statistics and only the study of each individual case, likewise the recognition of the clinical type of the process left to itself, will allow one to estimate the results. The writer is of the opinion that, generally speaking, the procedure will not deceive the hope it offers, if the following indications are adhered to, namely, (1) absolute indications, a unilateral fibrous process or even cavernous fibroid process. (2) Relative indications are the same cases with small torpid foci in the opposite lung. (3) Symptomatic indications: chronic ulcerative pneumonic processes. (4) Vital indications: severe hemorrhage. (5) Contra-indications: extremely acute processes or cascosus pneumonic processes.

The Chemiotherapy of Bacilli Carriers.—B. Stuber has endeavored to accomplish disinfection of the gall-bladder, taking as a basis the following theoretical considerations. Cystine when ingested is transformed into taurin in the liver and then becomes combined with cholalic acid and forms tauro-cholates which are eliminated with the bile. A combination of cystine and Hg. injected should free the Hg. during the progress of these transformations and should disinfect the gall-bladder. All this is naturally Teutonic dreaming and will probably result in a "potent and infallible" product, issued from some Farbenwerke for the use of the over-gullible practitioner with the conviction that "Deutschland ist über alles" in medical science. The writer says that he has been able to verify the elimination of Hg. by the bile and by this means he has been able to relieve carriers of their typhoid bacilli, especially among convalescents from typhoid. After all is said, the reviewer would merely say that, in Anglo-Saxon practice, the use of calomel has been for years greatly appreciated in these circumstances and that the learned (sic) tirade of the German writer may be profitably put on the list of what we have known for some time. We would note, however, that a Teutonic product of real value, namely, urotropin, has been overlooked by the distinguished writer of this memoir, in so far as disinfection of the biliary tract is concerned.

Deutsche medizinische Wochenschrift.

February 21, 1918.

New Researches on Muscular Function.—V. Kries refers especially to Hill's discoveries. In muscular contraction, the production of heat does not take place during the act but after it has been accomplished. Therefore, it does not correspond to the extreme phase of contraction (tension or shortening), but to the

phases of preparation and recuperation. These data, which contradict the older teachings of Fick, throw a new light on muscular physiology. They cause one to admit the existence of a form of energy as yet unknown, an intermediary between thermochemical and mechanical energy displayed by the contraction.

The Pathology of the Hypophysis.—Th. Fahr records two cases of lesion of the hypophysis. The first one belongs to the morbid picture called "hypophysary cachexia" by Simmonds. The patient, a female, aet 50 yrs., had had amenorrhea since the age of 29 years, at which time she had pneumonia and "nervous fever" (Nervenfieber). Since then she had daily vomiting and tinnitus aurum. Among the clinical symptoms a normal blood pressure and slight cutaneous pigmentation. The patient died in a convulsive attack. Autopsy revealed macroscopic changes in the suprarenal capsules, which were small, but the histologic findings did not permit one to conclude that there was a functional insufficiency. On the other hand, the hypophysis which macroscopically appeared normal, presented microscopically a sclerous degeneration of the anterior lobe, but nevertheless it contained islands of normal parenchyma. The posterior lobe, which was quite intact, contained much pigment. The other viscera were normal. The second case offered a pharyngeal tumor which must be regarded as starting from the hypophysary canal. The clinical notes show nothing which points to an insufficiency in the functions of the hypophysis, regardless of the complete destruction of the neurohypophysis (posterior lobe). This case speaks against the attribution of the adiposogenital syndrome, because in this particular instance this syndrome had not even begun. The neoplasm had destroyed the organ although it did not interfere with its functions.

Wiener medizinische Wochenschrift.

March 9, 1918.

An Attempt to Control Young Venereal Subjects.—E. Finger (of ancient vintage) has come to the conclusion that the police system now in force is insufficient for the control of prostitution, as this trade is becoming more and more clandestine resulting from the influence of social changes, such as feminine emancipation and professions now occupied by women, etc. Still more, Finger has noted that since the war there has been a marked increase in the number of young venereal subjects. Out of a total of 1,000 patients he tabulates the following results:

MALES.		
Age Years	Before the war	During the war
15	1	8
16	3	9
17	11	26
18	27	68
Total...	42	111

FEMALES.		
Age Years	Before the war	During the war
15	12	16
16	22	40
17	33	66
18	62	91
Total...	129	213

As to measures for dealing with this condition of affairs, Finger believes that police visits to all low class hotels has given good results. (In the U. S. such visits might be fruitful in what are rated as first class hotels.) The treatment should realize the isolation of patients, as well as from their occupation. This result may be obtained by the creation of "work colonies," an ideal to which the writer aspires. Finger, with the genuine Teutonic love of the salacious, enters into the details of the first steps taken into the social mire by the young girls of Vienna, upon which it is unnecessary to insist, but grievous from the fact that it is an evidence of senile decay in a brain once fertile in good things.

Nederlandsch Tijdschrift voor Geneeskunde.

January 25, 1918.

Intratracheal Treatment of Bronchial Asthma.—De Levie refers to an article by Einthoven published in 1892 in which was demonstrated the fact that asthma is due to spasm of the bronchi and is not dependent in any way upon the activity of the diaphragm. This view had long been upheld on theoretical grounds. Trousseau, himself an asthmatic, regarded the catarrhal component as unessential and made of asthma a nervous phenomenon. Biermer held similar views but laid more stress on the catarrhal component, regarding the congestion as a determining cause of the paroxysms. Traube, on his part, saw in the catarrh the primary, in the paroxysms the secondary factor. Einthoven's experiments did not dispose of the catarrhal theory. Recently it has been shown that asthma may be a purely anaphylactic phenomenon in which the lungs are not congested, but anemic and also dry. Asthmatics studied with the bronchoscope present a red and swollen mucosa, while immediately after a paroxysm the latter may be seen to be normal. But finds of this sort are by no means of uniform occurrence. Eosinophilia in the sputum is seen in the experimental anaphylactic case no less than in the catarrhal case in man. The phenomenon is also seen in angioneurotic edema. From one angle asthma is a vasomotor affection like urticaria, angioneurotic edema, mucous colic and other affections. These may also appear as anaphylactic phenomena, and as we know, anaphylaxis is acquired idiosyncrasy. But numerous other moments occur in the causation of asthma. It may be purely psychogenic while some writers have always seen the operation of a reflex element—in fact, asthma has been termed a reflex neurosis. If the method of cure shows the nature of the disease the intratracheal insufflations, which cause the greatest relief—those which contain novocaine and adrenaline—appear to indicate that reflex and hyperemic components play the major role. The author has used many drugs in this form of exhibition. The pioneers in this field comprise Pieniazek, Novotny and Ephraim and he has tested the substances recommended by them. In addition to cocaine and substitutes and adrenaline, he has tested various astringents and menthol, with special reference to the interparoxysmal period. Treatment during the interval was applied twice, then once weekly and later at longer intervals. The author's cases were associated either with chronic bronchitis or emphysema and the results, after several months of treatment, were very satisfactory. Of 15 patients treated 7 were cured, i. e., have remained free from paroxysm for one year; 6 are notably improved and 2 unimproved.

Il Policlinico.

February 1, 1918.

Peripheral Radicular Pseudotabes of Traumatic Origin.—Mendicini sums up his minute description of a case as follows: the syndrome presented included amyosthenia of the lower extremities, more accentuated to the right, associated with muscular hypotonia, abolition of the Achilles reflex and patellar reflex to the left, Romberg synaxatic gait, lancinating pains and intermittent paresthesiæ. There were also sensory disturbances having a radicular distribution, interesting especially certain lumbar segments on one or the other side. The entire syndrome followed a trauma of the lowest lumbar vertebra, the immediate result of which had been a complete paraplegia. The resemblance to true tabes was so pointed that one must ask whether the latter had not already been present at the time of the injury. It is true that in tabes the early manifestations appear at a higher level—the dorsal spinal, but exceptions occur. These symptoms comprise areas of tactile anesthesia which are demonstrable in the mammary area and upper extremities. But the author has recently studied a tabetic in which there were no sensory anomalies above the umbilicus. Tabes might, of course, have been excluded by absence of well known symptoms, although these could appear at a later period. The x-ray also showed that there was a lesion of the cauda equina. To go a little into history, the late Professor Dejerine described his neurotabes in 1883-4 and was promptly fol-

lowed by numerous clinicians whose studies elaborated the picture of polyneuritic pseudotabes. But the latter affection was never traumatic in origin, being the result of alcohol, arsenic or other toxic principle. The author's case can be differentiated easily from neurotabes on other counts. A general survey of lesions of the cauda equina shows that the prognosis is always favorable, i. e. there is a fixed tendency to improve, even in cases which at the outset seem grave. The lesion is extrameningeal and hemorrhage into the vertebral cavity is absorbed, so that after initial paraplegia we note the evidences of pseudotabes.

Emotional Traumatic Dystrophy in the War Zone.—Pighini refers to post traumatic conditions which do not appear to stand in direct relationship with the actual wounds. In other words, conditions in which a reflex component is usually imagined. The lesions in question are seen to be dystrophic. To what extent a psychogenic element is present has been much debated. There are numerous symptoms which point either to a psychic or endocrine mechanism. To throw some light on the problem, the author has made much use of the exhibition of certain alkaloids and harmonic principles. Adrenaline does not provoke glycosuria nor does it influence the blood pressure. The only result is augmentation of the tremor. Atropine causes tachycardia. Pilocarpine causes salivation and sweating. Physostigmin reduces the frequency of the pulse when it is elevated. The patients show a remarkable tolerance to thyroïdin and often profit by its use. Thus far the problem defies all attempts at solution, despite the indisputable evidence of this or that factor.

Finska Läkarsällskapet's Handlingar.

December, 1917.

On the Complement Fixation Reaction in Scarlatina and other Exanthemata of Childhood.—Nysten refers to the occasional appearance of the Wassermann reaction in scarlet fever, which fact induced him to develop the general study of complement fixation in these ailments. Naturally he was interested chiefly in the differential diagnosis of scarlatina. He first used an excess of complement and studied large quantities of serum with negative result. He then made an antigen out of a scarlatinous organ, and also used large amounts of antigen with small quantities of complement. From this experiment he learned that such antigen is not specific, differing in no wise from normal organ antigen. In using complement in the smallest hemolytic dose he obtained a positive result after two hours' standing at 37°, most marked in the second and third week and most frequently in cases with glandular swellings. In a series of controls he obtained no positive reactions. He also used cholesterin antigen with a small amount of complement and also obtained some positive results under the very same conditions. With streptococcus antigen from throat swabs he obtained no positive result. In measles he was unable to provoke a complement fixation but in variola he used an antigen from the pustules and obtained a positive reaction many times, usually on the second day of the outbreak. No complement fixation could be obtained in any case of varicella.

Various Sugars in the Diet of Nurslings.—Nyberg tested lactose, cane sugar, dextrin, maltose, dextrose, etc., in respect to their individual tolerance and food value. A proprietary preparation was found in this connection to correspond closely to the nutrient sugar long ago devised by Soxhlet and composed of maltose and dextrin. The same association is found in varying degrees in other well known proprietary foods, a fact of considerable significance.

Pregnancy Sepsis.—A case reported by Siemerling which might have been comprised under gravidity toxicosis was found to have quite a different motivation. The patient suffered from incoercible vomiting, polyneuritis and polyneuritic psychosis. Artificial abortion failed to save her life. Autopsy showed that the woman was suffering from streptococcus encephalitis, together with neuritis and myositis.—*Correspondenz-Blatt für Schweizer Aerzte.*

Book Reviews.

AN INTERNATIONAL SYSTEM OF OPHTHALMIC PRACTICE. Edited by WALTER L. PYLE, A.M., M.D., Philadelphia, Member of the American Ophthalmological Society. **MEDICAL OPHTHALMOLOGY.** By ARNOLD KNAPP, M.D., Professor of Ophthalmology, Columbia University; Executive Surgeon, Herman Knapp Memorial Eye Hospital. With 32 illustrations. Price, \$4.00. Philadelphia: P. Blakiston's Son & Co.

DR. ARNOLD KNAPP has presented in the volume under notice a full description of ophthalmological practice. The first part of the book is taken up with an exhaustive illustrated description of ophthalmological anatomy, and particularly of the nervous system connected with sight. In this portion of the work Prof. Otto Marburg of Vienna cooperated. The diseases of the nervous system affecting the sight are dealt with at considerable length. The chapter discussing diseases of glands with internal secretions concerned in eye affections, though brief, is of great interest. The toxic amblyopias are subdivided into groups. The infectious diseases, circulatory diseases, diseases of the respiratory and digestive tracts, diseases of the kidneys, diabetes, diseases of the female generative organs, osseous system, skin disease are all considered in their relation to eye affections. Lastly, hereditary eye diseases are dealt with. The object of this book is to give the essential of what is known of the relations of the various diseases discussed to the eye at the present time. The work is well illustrated and should prove of great use to eye specialist as well as general practitioner.

THE DISPENSATORY OF THE UNITED STATES OF AMERICA. Twentieth Edition. Thoroughly Revised. Largely Rewritten and Based Upon the Ninth Revision of the United States Pharmacopoeia, 1914. By JOSEPH P. REMINGTON, Ph.M., F.C.S., late Professor of Theory and Practice of Pharmacy in the Philadelphia College of Pharmacy. Chairman of the Committee of Revision of the Pharmacopoeia of the United States. HORATIO C. WOOD, JR., M.D., Professor of Pharmacology and Therapeutics in the University of Pennsylvania; Vice-Chairman of the Committee of Revision of the Pharmacopoeia of the United States of America. SAMUEL P. SADTLER, Ph.D., LL.D., Former Professor of Chemistry in the Philadelphia College of Pharmacy; Member of the Committee of Revision of the Pharmacopoeia of the United States of America. CHARLES H. LA WALL, Ph.M., Associate Professor of Theory and Practice of Pharmacy in the Philadelphia College of Pharmacy; Secretary of the Committee of Revision of the Pharmacopoeia of the United States. HENRY KRAEMER, Ph.G., Ph.D., Professor of Botany and Pharmacognosy in the University of Michigan; Member of the Committee of Revision of the Pharmacopoeia of the United States of America. JOHN F. ANDERSON, M.D., Director of the Research and Biological Laboratories of E. R. Squibb & Sons; Member of the Committee of Revision of the Pharmacopoeia of the United States of America. Philadelphia and London: J. B. Lippincott Company, 1918.

THIS Dispensatory is really a monumental work. Issued first in 1833, in a somewhat modest form, it has now become a veritable vade mecum of facts concerning medicinal substances. It is a mine of information and is almost all inclusive so far as medicinal treatment of whatever kind is concerned. In order to show the manner in which this Dispensatory has increased in size it may be of interest to note its enlargement since the issue of the first edition. The first edition consisted of 1073 pages, while the present consists of 2010. An especially fortunate circumstance in the compilation of this work is that the editors have been peculiarly well fitted for the task, and, of course, to their labors is due the success of the undertaking. A great loss to American pharmacy has been sustained by the death of Professor Remington, one of the editors since 1880, and who, although gravely ill, kept at his post until the manuscript had been completed. Since 1907 vast progress has been made in pharmacy and medicine and in consequence a thorough revision of the work had been called for. Indeed, the book had been almost entirely rewritten. The arrangement of the

book is excellent, all the valuable features of the nineteenth edition having been retained. Chemical incompatibilities have been accorded great prominence, a summary of the incompatibilities of the more important drugs having been placed immediately before the description of their therapeutic value. Articles on vaccines have been added and those dealing with the various serums have been enlarged considerably. The Harrison Antinarcotic law and the regulations of the Internal Revenue office in connection with it are given in extenso. The Food Inspection decisions under the Food and Drugs Act of 1906 are set down in the first part of the book. This affords a commercial and valuable opportunity for wholesale and retail pharmacists to obtain a knowledge of these regulations. Part I of the Dispensatory contains the discussion of all the remedies recognized by either of the two Pharmacopoeias used by English-speaking people. In Part II the national formulary and non-official drugs are considered by themselves. In Part III the tests and test solutions of the two pharmacopoeias, weights and measures, the art of prescribing medicines, an abstract of the national formulary IV and cognate miscellaneous matters are dealt with. The drugs are arranged in alphabetical order. It may be said that the description of the different medicinal substances is remarkably comprehensive and extremely accurate, and the entire volume is simply replete with information much of which is practically indispensable to the physician and general practitioner.

ELEMENTS OF HYGIENE AND PUBLIC HEALTH. A Text-book for Students and Practitioners of Medicine. By CHARLES PORTER, M.D., B.Sc., M.R.C.P. (Edin.), of the Middle Temple, Barrister at Law, Medical Officer of Health, Metropolitan Borough of St. Marylebone; Examiner in Public Health University of Edinburgh; Member of Board of Examiners, Royal Sanitary Institute and Sanitary Inspectors' Examination Board; Formerly Tutor in Public Health, St. Bartholomew's Hospital, etc.; Author of "Sanitary Law and Practice" (with Dr. William Robertson), "School Hygiene and the Laws of Health," "Sanitary Law," etc. With 98 illustrations. Price, \$4.15. London: Henry Frowde and Hodder & Stoughton, 1917.

THIS is a very attractive volume; its size is handy, and not repellent; its contents are new and not merely revised; the author has had a wide experience in teaching, writing, and examining on the subject matter of this book. The work deals with personal hygiene, public hygiene, and disease (including origin and spread of infectious diseases, the notifiable diseases, prevention of infectious disease, and non-notifiable diseases), tropical diseases, animal parasites, occupational diseases and industrial hygiene, offensive trades and trade and other nuisances, climate and meteorology, disposal of the dead, food, air, soil, water, housing, ventilation, warming, lighting, removal and disposal of refuse and waste (house drainage and drains, sewers and sewage, household refuse), the existing house, school hygiene, public health administration, sanitary law, and vital statistics. The author has written a most interesting volume; the different topics are treated briefly, but authoritatively, and there are a sufficient number of useful illustrations. Of course, the sections on public health administration and sanitary law are based on English law, custom, and requirements. The price of the book seems unnecessarily high, and will hardly aid its sale.

ANAPHYLAXIE. ANTIANAPHYLAXIE. Par. A. BESREDKA. Preface de E. ROUX. Price, 4 francs. Paris: Masson & Cie., 1917.

THIS little volume, dedicated to the author's late chief, Metchnikoff, is the labor of one of the leading authorities on anaphylaxis, who is, moreover, the creator of our knowledge of antianaphylaxis. The first portion of the book is, therefore, a preparation for the consideration of the latter subject. From the sensibilizing injection the author leads up to the toxic or loosening injection. The culmination of the book is Chapter V., in which is discussed the principle of antianaphylaxis, as illustrated by the vaccinating injection. The last two chapters comprise really a supplement which deals with miscellaneous phenomena of anaphylaxis and the various theories of its nature.

Society Reports.

AMERICAN ASSOCIATION OF IMMUNOLOGISTS.

Annual Meeting Held March 29 and 30, 1918.

JOHN A. KOLMER, M.D., OF PHILADELPHIA, PRESIDENT.

(Continued from page 835.)

SESSION WITH THE AMERICAN ASSOCIATION OF PATHOLOGISTS AND BACTERIOLOGISTS.

Various Immunological Reactions in Glanders.—Dr. G. B. WHITE of New York read this paper. Discussing glanders infection Dr. White said one horse among a number of serum horses apparently in good condition got ill, died, but had no autopsy. A week later another horse had to be killed. The eye test then was put on all the horses of the stable. Six animals reacted. Complement fixation was also done. Upon positive eye tests the horses were killed and autopsied. The tests showed similarity to the results in tuberculosis. All horses in which lesions were found gave positive subcutaneous reactions, but negative complement fixation and agglutination. Three of the horses autopsied did not show lesions, but perhaps the examination was not thorough enough. Those which showed lesions at autopsy had given positive subcutaneous tests. Those with positive eye tests gave positive subcutaneous tests, but the opposite statement did not hold. A positive complement fixation did not always go with positive eye test. The complement fixation was not considered particularly reliable in this condition. After the injection of mallein to the eye, there would appear a positive complement fixation and agglutination, in a horse originally negative. The most reliable test is the subcutaneous test, which can be found positive at the time of early lesions. Later the eye test appears, lastly complement fixation and agglutination. After an injection of mallein the subcutaneous test would be refractory for three weeks, but after six weeks it would be apparent again.

Dr. WM. H. PARK of New York said there was absolutely no knowing what reaction could be relied upon in serum horses. Very few horses would pass all three tests,—complement fixation test, agglutination test, and subcutaneous test. There had been a question as to what horses should be admitted to the market for food, and it was found necessary to alter the standard so as to admit horse meat to alleviate the food shortage.

Dr. A. P. HITCHENS said that it was his feeling that many more horses reacted to the subcutaneous test than had glanders. He did subcutaneous test as well as eye tests and complement fixation, and he depended upon complement fixation. He found they had to accept some horses which gave positive subcutaneous tests. They had had no trouble with those animals. Reading of the subcutaneous test required considerable skill, the symptoms varied. Just what was a positive subcutaneous reaction and what was not, was open to question and would depend largely upon the individual making the examination.

Dr. G. B. WHITE said he quite agreed that Dr. Hitchens might find a positive subcutaneous test, with no active glanders. It was much the same as tuberculosis. One might have a healed lesion. Unless the horse with this reaction was put under any particular strain, there was very little chance of glanders breaking out.

Active Immunity in Those Immunized Against Diphtheria.—Dr. WILLIAM H. PARK of New York read this paper. In testing different species of animals, some were found to have no immunity, some were entirely immune, and again there were a group in which some were immune and some were not. Guinea pigs had no natural immunity. The horse could be immunized very rapidly and nearly always produced considerable antitoxin. At the end of twelve months the developed immunity had dropped to the original level,—1/50 to 1/4 units. Of human beings, a number were not immune. Dr. Zingher had made interesting tests on groups of babies: first immune babies with immune mothers; they remained immune. Another series were not im-

mune; they were immunized and became immune. Dr. Zingher tested children in institutions and found that fourteen months after immunization, those that had received but one injection of antitoxin were as immune as those that had received two or three injections. The development of immunity was, however, slower. Results were very encouraging. A great number of children remained immune. It seemed as if the acquired immunity would be as permanent as the natural immunity. Of four hundred and four children tested, three hundred and ninety-six remained immune. Two of these never became immune. It would seem practical to immunize infants at the period of life when there was the greatest danger, when they had no immunity. Infants under one year, immunized, seemed to retain the immunity.

Dr. A. F. HESS of New York said that the use of toxin-antitoxin mixtures had made a great difference in infant asylums. Formerly there used to be about fifteen cases a year with three or four deaths, and since the use of antitoxin there had been no diphtheria and no deaths. In one hundred and fifty cases injected and followed for from one to two years, 98 3/4 per cent. had remained immune. As regards the best time for immunization, too early injection could be made, because children carried over some immunity from their parents and would thus be immune the first months of life, and yet have no immunity later in the first year. Fifteen per cent. of cases lost immunity in the first year; 10 per cent. in the second year; 5 per cent. in the third year. If no protection were given to susceptible infants, there would be many more cases of diphtheria in institutions. This protection would absolutely do away with diphtheria in institutions.

Dr. J. A. KOLMER asked the nature of the reaction following the toxin-antitoxin mixture. Was a single dose advocated or was it wise to give a second?

Dr. WM. H. PARK said that children who had received one injection, would be immune by the end of a year, but if there were any immediate danger it would be well to test again by the Schick test, and, if necessary, to give another injection. The method was being used in the Navy and in the Army, as diphtheria was not always recognized at once, and if the troops were immunized, one did not have to worry about carriers. In a few cases there was a slight toxic effect. If the protein in the toxin-antitoxin mixture could be controlled, it would become a very harmless procedure.

Dr. J. F. ANDERSON asked if there was quick deterioration in the mixture.

Dr. W. F. PARK said they always used old toxin which had dropped in toxicity. One-third more antitoxin was given than was actually required.

A Simple Method for Blood Cultures.—Drs. J. G. WURTS and S. W. SAPPINGTON described this method. The interest attaching to positive blood cultures made it essential that there should be some improvement in technic. It was considered necessary, in view of the bactericidal effect of the leucocytes that the serum should be removed. The blood was, therefore, diluted with sterile, distilled water, in dilutions of 5, 10, 12, 20, and 25 per cent. blood to water. The growths on diluted blood were more readily obtained than with pure blood. The best growth occurred on a 30 to 40 per cent. dilution. This seemed a specially good medium for pneumococci. It had always been found impossible in other ways, to get a good, rich growth in severe cases. In cases of *B. typhosus* infection, or with streptococcus infection, the diagnosis could be made within twenty-four hours. The results were equal to those with the use of bile, and the simplicity of the method made the use of it, outside of a hospital, extremely easy and satisfactory.

Bacteriological Study of Postoperative Pneumonia.—Miss MIRIAM OLMSTEAD of New York read this paper. She had studied one hundred and thirty cases of postoperative pneumonia, and had recorded the recovery of a pathogenic organism in thirty-one cases,—a percentage of 23.8. Two cases had a pneumococcus I, in the blood stream, one of these pneumococcus I in pre- and postoperative sputum. One had pneumococcus II, in the sputum, pre- and postoperative, and the urine was precipitated by pneumococcus II serum. In two cases with an atypical II in pre- and postoperative sputum, the etiology was established, in one by a positive ag-

glutination test of the patient's serum, and in the other by a urine precipitin reaction with Type II serum. Type III was established as the inciting factor in five cases; one had a blood culture; from one the organism was obtained by lung cultures at autopsy; the blood of two agglutinated the Type III, recovered from the post-operative sputum. The urine of these two, and one other, who had Type III in the preoperative sputum specimen, gave a precipitin reaction with Type III serum. In eighteen cases Type IV was the factor, once being recovered from the blood, and seventeen cases gave a positive agglutination reaction with strains from the sputum. In one of these cases the urine precipitated with Type IV serum. In one case a hemolytic streptococcus was found in the blood stream and in another a hemolytic streptococcus in the sputum gave a positive thread reaction with the patient's serum. A mucoid streptococcus was found in sputum and chest fluid of one case. Some of these organisms were undoubtedly the inciting factors of other post-operative pneumonia cases, but no direct evidence could be obtained as to this view. As Whipple has stated, the most common factor was Type I. This was found to be recovered in either pre- or postoperative sputum in ninety-seven of one hundred and thirty cases studied. This appeared significant.

Dr. A. F. HESS of New York asked if pneumonia developed among cases where the pneumococcus was absent, if so, how many? In what percentage of cases was there discrepancy in the type of pneumococcus in the pre- and the postoperative sputum where pneumonia developed?

Dr. J. A. KOLMER asked how many patients, with pneumococci in the blood stream, died. How many showing precipitin reaction died? He was under the impression that persons showing the precipitin reaction had rather a bad prognosis.

Miss M. OLMSTEAD said that those persons who gave a urine precipitin test did not seem to have a bad prognosis. No case died. Three patients had Type III in the sputum and gave precipitin test reactions. None died. In reply to Dr. Hess, in three cases there were postoperative findings of pneumococci in the sputum, where they were nondemonstrable preoperatively. The majority of cases had pneumococci pre- and postoperatively.

Active Immunization Against Pneumonia.—Dr. R. KOHN of Boston read this paper. This study he said was not new. Lister had given large doses of heated killed pneumococci of virulent types at six to seven day intervals. In active immunization against all types agglutinins and opsonins could be demonstrated eight months afterward. Reports constantly showed the desirability of protection against pneumonia. It was believed, however, that immunity against pneumonia was of short duration. It was found that a horse immunized three years ago, with no injections for one and one-half years, gave serum that protected against 0.1 c.c. This serum had originally protected against 0.2 c.c. Tests were made to discover the protective power of blood serum against infection in white mice, injected intraperitoneally. It was found that normal human serum would protect mice against the M.L.D. Some serum protected against a particular strain. It was found that most persons could be immunized against types one and two, possibly three, and that after nine months the immunity had not diminished. It could last one year, possibly more. There was no evidence that it was absolutely protective. Adverse conditions might result in a lowering of the danger point.

Dr. AUGUSTUS WADSWORTH of the New York State Health Department said that he felt a great deal of interest in this work. Different individuals, exposed to different pneumococcus infections, manifested different degrees of immunity from time to time. He had done experiments on rabbits in which he had sought to produce lesions and to get some immunity. He felt that pneumococcus immunity in the human subject was a very important question.

Dr. WM. H. PARK said that in the south of France there was a great deal of pneumonia at one camp. The men were vaccinated with cultures from the camp and in eighteen days the pneumonia disappeared. Another camp used the same vaccine and the results were negative. He could not say whether this was a coincidence.

Using the culture of a camp 50 miles distant did not seem to correspond to the type of infection. It was striking that the cessation of the epidemic in the camp followed the use of the vaccine.

Production of Pneumococcus Serum and the Corresponding Curves Obtained by Protection and Agglutination Tests.—Dr. G. B. WHITE of New York read this paper. He said that the unusual demand for antipneumococcus serum had urged them to put forth every effort to increase the yield from their serum horses. The problem had arisen as to how best to spare the horse. The conservation of the animals was an important thing. The heavy draft horses seemed to stand the bleedings better; the lighter types did not last long. A vicious horse with "a great deal of game" was the best type of producer. Type one strain in virulent culture was necessary to produce type one serum. The cultures were transplanted three or four times, using Witte peptone, or, if not obtainable, Fairchild or Parke Davis preparations. The culture was heated three-quarters of an hour at 56° C. and made into a vaccine which was used in a series of six injections. If live organisms were used, the preparation was made fresh each time and injected intravenously. Three daily injections of dead cocci were made, then three of living; wait a week and repeat, and six days after the second weekly injection the horse was bled. The dosage is regulated by temperature reactions which should not be above 100°. Horses are bled before and after immunization. Three or four days then elapse before giving an injection. Agglutination seems to be an uncertain indication of immunity and agglutinating power changes rapidly, according to cultural conditions; also the condition of the horse. A standard method had been evolved by which 1 c.c. of serum protects against 0.1 c.c. type one pneumococcus. The serum is tested against the maximal amount of culture it will neutralize; also the smallest amount of serum which has protective power is estimated. There was no proven deterioration of serum. There seemed to be no parallelism between agglutination power and protection power, and the former standard would probably be discarded as unreliable.

Dr. A. P. HITCHENS said he could congratulate Dr. White on the results obtained in the rapid immunization of the horses. This was an especially important point at this time. In regard to bleeding, what was the plan of bleeding as regards the time of injections? What was the interval between the injections?

Dr. J. F. ANDERSON said they had been using a method of six daily injections, in three courses, with seven-day intervals. The horse could be bled in thirty-two days. A standard was made to protect against 0.1 c.c. culture, 0.2 c.c. culture, and 0.3 c.c. culture.

Dr. G. MCCOY of the Hygienic Laboratory said that he was glad to hear Dr. White bring out the point of the unreliability of the agglutination power as compared to the protection value. They had had strains sent back marked N. G. because they did not agglutinate type one pneumococci, but still there was a high protection power. All commercial sera before being sent out were tested by the hygienic laboratory.

Dr. A. WADSWORTH asked if the high protective serum had any agglutination power at all.

Dr. MCCOY said it had no agglutination power at all. Dr. WADSWORTH asked was it controlled and was told "Yes."

Dr. J. B. WHITE said that the horses were bled six days after the last injection. Two courses of injections preceded bleeding. They had lost four horses from pneumococcus infection. The first two were protective against 0.1 c.c. culture. Both animals had lobar pneumonia of type one kind. One horse died of pneumothorax. Another animal had constantly elevated temperature. It was found to have 125 pneumococci to the cubic centimeter of blood. It died of endocarditis. The organism was serum fast. That horse never protected. Another horse produced blood which on blood agar showed 100 paratyphoid bacilli. The serum agglutinated the strain 1/5000.

Rapid and Simple Method for the Determination of Type of Pneumococcus in Sputum of Lobar Pneumonia. Dr. CHARLES KRUMWIEDE of New York presented this communication. This was based on an attempt to dissolve the pneumococci and get the antigen. The sputum

from the lung being rich in albumin, this was coagulated by boiling water and the coagulum extracted to get the precipitin reaction. The coagulum was added to saline if the latter was necessary. It was again placed in boiling water to get soluble antigen. The broken clot was centrifuged and the clear supernatant fluid used for the test. With 0.2 c.c. of serum in the test tube the antigen was placed upon the serum, and tubes were placed in the water bath. Contact rings would be then noticed. The tubes should be shaken for twenty minutes and the observations could be read within half an hour.

Dr. O. W. H. MITCHELL of Albany said he had gotten the same results by the method of extracting with sand. He was convinced as to the specificity of the reaction. The rapidity and simplicity of the method made it an excellent one. Their sera were furnished by the New York State laboratory. The tests had been checked by Dr. Wadsworth and invariably when the sputum had reacted definitely his report had corroborated their results. Young rats had been found easier to procure than mice for pneumonia work. Children kept them as pets and a few inquiries generally resulted in getting as many as were necessary. Half-grown rats were preferable to mice. The peritoneal cavity is larger.

Experiments with Cancer Tissues and Normal Tissues, Also with Artificial Systems.—Dr. G. H. A. CLOWES of Buffalo presented a summary of this work. He had produced similar results to those of Osterhaus and Loeb. The size of the pores of a filter, he would state, had no relation to the permeability of the filter. The factor of importance was the lubricant. A suspension of rouge would not pass through a filter, but if salt were added the surface tension was lowered and the passage of particles through the filter took place. Thus it could be said that salt solution was the most toxic possible substance, as far as permeability of tissue was concerned. It was found that rapidly growing tissues had relatively greater conductivity and less resistance. If the ions could pass through more easily, the permeability—therefore conductivity—of the tissue was greater. In systems of drops, high surface tension produced very large drops, while lowered tension produced many drops, to the point of a continuous stream. In regard to human blood, this was equal to 0.15 NaCl. Protoplasm was a delicate mechanism, controlled by the nicest balance of soaps, lipoids and fats. The question of anaphylaxis was bound up with this matter of balance. Pathological conditions were results of disturbances of the balance of soaps and fats in emulsion. The protein was really nothing but a mesh or network which served to support this delicate emulsion of protoplasm.

Dr. JAMES EWING said that in listening to the philosophical presentation of Dr. Clowes the previous day, he had suggested that it would be well for the speaker to attempt an interpretation of his observations in terms intelligible to the pathologist and the immunologist. It had seemed to him that they were on the verge of seeing a great light, which never dawned. One wished to know how physical systems had a direct bearing on pathological conditions, especially in fatty degeneration, although Dr. Ewing said he was prepared to admit that the fatty changes were not as simple as the soaps. This line of work corresponded to that done by Nobel. The phenomena of anaphylaxis would probably be found to fall in line with all these observations. Dr. Ewing said he felt he could congratulate Dr. Clowes on having made his experiments intelligible—to the pathologist.

Dr. H. ULRICH said that he felt that surface tension was a vital factor in formation of spores. *B. subtilis* would not grow on media with lowered surface tension. *B. anthracis* entirely loses its pathogenicity when grown on media with lower surface tension. It would then produce no symptoms whatever. When blood serum is added to culture media the tension is lowered. The tension had to be suited to the growth of the organism. This work of Dr. Clowes was very suggestive.

Dr. J. BRONFENBRENNER said that this question of surface tension was not new. The reaction to the antigen was based on change in surface tension. When Abderhalden's work was done it was shown conclusively that where the serum was induced to undergo digestion there was decrease of surface tension. Ger-

man scientists had suggested that photometric phenomena might be parallel. The phenomena of ferment action might also be a question of dispersion.

Dr. G. H. A. CLOWES said that he felt immensely interested in the observation about anthrax spores. That corresponded with his own findings. Anyone who had seen the amoeboid movement and spore formation and separation and phenomena in yeast would be convinced as to the importance of surface tension. He had got objects that looked exactly like leucocytes and shown them to the pathologist, who said they were leucocytes. This was simply by getting a perfectly balanced emulsion. He had also done work with organic poisons, in regard to their hydrogen ion concentration, Dr. Bronfenbrenner had mentioned the myostagmine reaction. That was in accordance with Asterley's work. He let drops fall into the air instead of into media. Ferment action was definitely due to surface tension changes. Perfect contact has been effected and dispersion occurs, or aggregation takes place.

The Chemotherapy of Experimental Pneumococcus Infections.—Dr. J. A. KOLMER stated that the object of this work was to produce drugs possessing high pneumococcal activity, yet of sufficient low toxicity to admit a dosage which would increase the pneumococcal activity of the body fluids, against acute pneumococcal infection. At the present time quinine derivatives were the only known drugs which exerted this effect to any marked degree. Work has been done with mercurial compounds injected directly into the lung, but this had not proved of value. Experiments by Drs. Schamberg, Raiziss and Kolmer had resulted in the discovery of mercurial compounds, possessing marked bactericidal properties for pneumococci in the test tube. These agents were combinations of mercury with: (a) Naphthol and Naphthylamine; (b) Phenol; (c) Benzidine; (d) Aminophenyl-arsenic acid; (e) Guaicol. Subcutaneous or intramuscular injections of these drugs were made two hours before a lethal dose of pneumococci into mice. The work was carefully controlled. A Type I strain of pneumococcus was employed throughout. The results of this work showed that all of the ordinary soluble salts of mercury and many of the new compounds worked with, were found to be without appreciable effect in protecting mice against a lethal dose of pneumococci. Often it was found that larger doses of these compounds hastened death by reason of summation of toxic effects.

Drs. J. A. KOLMER and E. STEINFELD of Philadelphia recorded the results of their experiments with Morgenroth's drug, optochin, a hydroquinone derivative, (methylhydrocuprein) which was found to have a high pneumococcal value, in the test tube and in the living animal, although its high toxicity would not allow of a sufficient amount being administered to influence lobar pneumonia. This drug, administered subcutaneously, in doses without protective value, usually increased the protective value of antipneumococcus serum, Type I, in a slight but definite manner, in severe infections among mice, with homologous pneumococci. Secondly, several of the commoner compounds of quinine, as quinine and urea hydrochloride, quinine hydrobromide and quinine chlorodisulphates administered subcutaneously, in doses without appreciable effect upon fatal pneumococcus infections, sometimes increased the protective power of antipneumococcus serum, but to a lesser extent than that afforded by ethylhydrocuprein hydrochloride. Ordinary salts of mercury and several synthetic compounds of mercury, were without effect upon the protective power of serum in severe infections.

Studies on the Toxicity of Pneumonic Lungs.—Drs. J. A. KOLMER, C. WEISS and E. STEINFELD of Philadelphia read this paper. Numerous experiments were cited and the results found by these investigators would show that: (a) Salt solution extracts of human lung in the stage of grey hepatization in pneumococcus lobar pneumonia, were found to be more toxic for experimental animals than similar extracts of normal lung tissue. The method of extraction influenced the toxicity of both extracts. (b) Lethal doses of extracts of both pneumonic and normal lung tissue injected intravenously usually produced anaphylactic symptoms. (c) Sterile extracts of pneumonic lung tissue in dogs, removed forty-eight hours after intrabronchial insuff-

flation of virulent pneumococci, were more toxic than similar extracts of consolidated lung, following intrabronchial insufflation of sterile aleuronat in suspension, and both of these were more toxic than equal quantities of extract of normal dog lung. (d) The toxicity of normal and of pneumonic lung was decreased by heating, drying, and passing through a porcelain filter. (e) Extracts of human pneumonic lungs, during grey hepatization, were frequently hemolytic for guinea pig cells, whereas similar extracts or normal human and dog lungs, and of consolidated dog lungs following the intrabronchial insufflation of virulent pneumococci and sterile aleuronat, were generally non-hemolytic. The hemolytic activity of these products was neutralized by horse antipneumococcus serum, also normal rabbit serum; was reduced by heating and drying, and usually removed by porcelain filtration. (f) One extract of a human pneumonic lung in grey hepatization was found to neutralize partly the agglutinating activity of an antipneumococcus serum. (g) The nature of these toxic and hemolytic substances was unknown; it was probably allied to the protein fractions and might be partly responsible for the symptoms in lobar pneumonia, which were ascribed to toxemia.

A Skin Reaction to Pneumotoxin.—Mr. CHARLES WEISS and Dr. JOHN A. KOLMER present this communication. The work reported formed part of the studies on the properties of pneumotoxin and its probable role in the pathology of lobar pneumonia. The authors used the endocellular hemolytic toxin of the pneumococcus freshly prepared for each test by dissolving the washed living organisms (Type I), in solutions of sodium choleate. Guinea pigs previously sensitized, reacted to the intracutaneous injection of 0.1 c.c. of the toxin. Control animals gave uniformly negative results. Among human adult cases of lobar pneumonia the reaction was elicited as early as the fifth and as late as the thirteenth day of the disease (two days before and six days after the crisis, respectively). In children it was demonstrable about the same time, but was negative immediately or one or two days after the crisis. Patients recovering by lysis reacted as late as the thirty-second day. In general, the test was positive in all active cases.

Dr. A. P. HITCHENS asked had Dr. Kolmer taken into consideration the great increase of toxicity in tissues which undergo autolysis. A piece of liver digested in sterile salt solution for twenty-four hours would become extremely toxic.

Dr. R. R. MELLON of Rochester asked if these extracts of empyema fluid bore any relation to the aggressiveness of the disease.

Mr. WEISS, of Philadelphia, said it was very difficult to decide whether or not the toxicity or the pneumonic exudate was present or not in tissues undergoing autolysis. One could detect the proteins, proteoses, etc. Most of the experiments were done to detect substances called pneumotoxins, to which the toxicity of the exudate is due. The addition of autolysates would increase the toxicity. The hemolytic properties of the pneumonic exudate may not have been specific for pneumonia. They had been attributed to various fatty acids. Specific anaphylactic results were obtained by sensitizing guinea pigs by normal and pneumonic exudates. The latter was rich in fibrin and the reaction might have been specific to the fibrin.

Dr. JAMES EWING said that this work was an important step in the right direction. He did not feel competent to offer an opinion, but he wondered why the work of immunologists turned always to specific toxins and away from tissue changes which the pathologist was interested in. He believed that immunologists had been set back by over attention to Ehrlich's theories.

Dr. G. H. A. CLOWES asked were these substances soluble in fats and lipoids or in water. That was of vital importance in determining their characteristics.

Dr. J. KOLMER said they had no means of absolutely controlling this work in relation to aggressiveness. They tried to ascertain whether this toxic substance would retard phagocytosis of pneumococci in vitro.

Observations on the Use of Salvarsan in Acute Infections.—This work, a brief summary of which was given, was done by Dr. C. S. ALLISON, who had recently

died of lobar pneumonia, and in whom the Association lost a most promising and untiring worker. He had tried the effect of using salvarsan therapy in positive blood stream infections, due to various bacteria. Results from the use of the Dakin solution in infections of the uterine cavity were recorded together with the salvarsan injections. Good recovery was made. Experiments with the use of salvarsan in streptococcus bacteremia were recorded. The conclusions were that unless the primary focus of infection could be detected and removed, intravenous injections of salvarsan were of little use.

Preliminary Tests to Blood Transfusion.—Dr. ARTHUR F. COCA of New York made this presentation. There was, he said, little to add to this practically closed subject, but certain facts should be kept in mind in regard to blood constituents, where transfusion was required. Individuals fell into four groups in regard to the red corpuscles qualities. Two different agglutinable substances are present (a) and (b) and the plasma of human being contains iso-agglutinating substances—(A) and (B). It might be stated that (a) is never present with (A). All possible combinations of the substances, however, might occur in different individuals, as many as 4,000 having been demonstrated. The four groups are—I, with iso-agglutinable substances (A) and (B) in the plasma; II, with (BB) in the plasma; III, with (A); IV, substances lacking. Most individuals are Types I and II. Transfusion would be most favorable when donor and recipient belong to the same group. Most unfavorable results would arise when the recipient's plasma contained agglutinins for the donor's corpuscles. As regards technic:—venous blood is obtained, citrated, and the serum of the patient is mixed with washed corpuscles of the donor, and vice versa. If agglutination were present, it would do as much harm as hemolysis; hemolysis never occurs without agglutination. Dr. Coca gave the different techniques of various workers, Weil, Rous and Wright, which he had simplified by his method. One per cent. sodium citrate was used, one part to nine of patient's blood. One point to bear in mind was that the donor's blood, not being anemic, was richer than the recipient's blood. One part of donor's blood to nine of the patient's was sufficient. In this proportion agglutination would take place at once, if at all, and could be readily detected.

Dr. JOHN A. KOLMER of Philadelphia said he would like to refer to a technique which had been employed during the past year which was somewhat similar to that demonstrated by Dr. Coca; this was the microscopic method with Lee's technique. Two types were used: one containing 1 c.c. of sodium citrate in a dry test tube and one with blood. The blood from the patient and from several donors (separately) was brought to the laboratory. The corpuscles were not centrifuged; the clots were broken up in the platinum loop. Two drops of patient's serum was used with one drop of corpuscle suspension of each donor; then two drops of serum from donor and one drop of corpuscles from the patient. Observations were made at the end of fifteen minutes, when agglutination, if any, would be marked. This method did not attempt to group the blood which was not of practical advantage, unless in an army hospital where groups were tested, but it was a quick and practical procedure in the average case. Dr. Kolmer said he believed the opinion was gaining ground that these preliminary tests should be done. Some surgeons did not make use of them and transfused without paying attention to any tests. This would seem to involve certain risks to the patient.

Dr. A. F. COCA said that the choice of methods would lie with the individual and what apparatus he had at hand. These methods were much quicker than blood counting. All the apparatus would be available in any laboratory that does blood counting. As regards transfusion without preliminary tests, it was known that death had occurred from this procedure, and the surgeon might meet serious trouble. Eighty per cent. of persons fell into the first two groups and the chances were that the donor would fit the case, but this did not hold good in all cases.

Isolation, Purification and Concentration of Immune Hemolysin.—Dr. M. KOSAKAY read this paper: These studies were made in the Institute of Forensic Medi-

cine, Tokio Imperial University. The concentration of antibodies for the purpose of serum therapy, and the elimination of serum proteins in order to avoid serum sickness, were the objects of the research. Elimination of serum proteins was attempted by the precipitin methods employed in production of diphtheria antitoxin. Secondly, extraction of immune bodies by antigens and use of inorganic substances, such as charcoal, was attempted. Separation of antibodies from the antigenic substance was found possible. This was done with hemolysins, precipitins and other combinations by treatment with acids and alkalis. Antibodies were found to be coagulable by high temperatures. Use was made of the fact that immune reactions were slow in salt free media. The serum elements were removed by washing in sodium chloride, and the antibody in the final preparation could be measured. The corpuscles were treated with hypertonic sugar solution which does not produce hemolysis, the corpuscles thus remained intact with the hemolysins attached. Some antibodies were discharged into the sugar solution at ordinary temperature, but more were obtained by raising the temperature, to as high as 60° C., without producing hemolysis. Five-sixths of the antibodies were thus discharged and the concentration was found to be of some value. The optimum relation was found to be 4 c.c. of corpuscles and 20 c.c. of a 10 per cent. sugar solution; 15 minutes was found to be the optimum time of reaction. The supernatant fluid was found to contain hemoglobin, and the attempt was made to get rid of this protein. This was done by shaking the sugar solution with ether. This produced 3 layers: first, ether; second, gelatinous mass; third, clear layer of sugar and hemolysins. The latter was dialysed and sugar removed. When the sugar-free, salt-free solution was evaporated, the hemolysin was left and was 5/6 full strength. It was free from protein reactions.

Dr. WILLIAM H. PARK of New York asked if Dr. Kosakay had been able to separate the antibodies from the bacteria, as well as from the red cells.

Dr. JOHN A. KOLMER of Philadelphia asked if it were possible to secure the hemolysin alone from the immune serum by this method. With the antihuman system there was the trouble of hemi-agglutination. So far efforts had failed in securing hemolysin free from the hemiagglutination. Was the final solution free from this factor?

Mr. CHARLES WEISS of Philadelphia said that two years ago, working in the Health Department Laboratories, he had tried to produce anti-Schick hemolysins, free from red blood cells. Dr. Cahn suggested crystallizing the hemoglobin. If one could produce this by chemical means the technique would be simplified.

Dr. KOSAKAY said it was a good idea to make the hemolysin free from bacteria. It had not been tried. He had not been able to separate the hemiagglutination from the hemolysin. This was an important point to study.

A Rapid, Simple Method for Extraction of Precipitin Antigen from Bacteria.—Dr. CHARLES KRUMWIEDE of New York read this paper. This was not original, but it demonstrated the extraordinary resistance of bacterial precipitin antigen to both heat and chemicals. A very heavy suspension of bacteria was necessary for the technique. Antiformin was added and the mixture kept boiling till the bacteria were dissolved. Phenolphthalein was next added, then hydrochloric acid, finally alcohol. The solution was then dissolved to 20 times its volume with saline, to get rid of bacterial rests. The clear solution resulted in an extract to be diluted 50 to 200 times. The essential point was to start with a very heavy bacterial suspension. If not heavy enough, there would be very little precipitate. Acid-fast bacteria could not be used for this method, as they were not dissolved by the solution. The above method would produce the most concentrated form of antigen obtainable.

Dr. GEORGE SMITH of Glen Olden, Pa., asked if this precipitin antigen was as valuable as antigen for the production of other immune bodies, when employed as antigen.

Dr. KRUMWIEDE said he had tried to produce immune serum to the antigen. It did not produce any antibodies.

(To be concluded.)

Therapeutic Hints.

Lumbago.—Whitla uses the various types of salicylates for relief of the pain, such as aspirin 15 gr., salicin 20 gr., salophen 10 gr., or salol 10 gr., given three times daily, usually with plenty of water to drink, and the following application applied on lint over the affected part of the back:

℞ Liniment. belladonnæ 5ij
Liniment. aconiti 5 iss
Liniment. chloroformi ad. 5vj

M. Sig. For external use.—*Dictionary of Treatment.*

An Ointment for Microparasitic Skin Diseases.—Pied offers the following modification of Reclus' ointment (*Jour. de Médecine et de Chirurgie Practiques*):

℞ Glacial carbolic acid,
Salicylic acid āā 1
Resorcinol 2
Camphor (powdered),
Antipyrine āā 5
Balsam of Peru 6
Vaseline q.s. ad 100

The carbolic acid, salicylic acid, resorcin, and camphor should be dissolved in a small quantity of alcohol. The antipyrine is dissolved in its own weight of sterile water. The mixture is incorporated with the vaseline, and the balsam of Peru thoroughly mixed with it in a mortar.—*The Practitioner.*

Eczema and Other Irritating Dermatoses.—

℞ Bismuthi oxidi 5ij
Acidi oleici 5ij
Cerae albæ 5vi
Petrolati 5ij 5ij
Olei rosæ mxi

M. et fiat unguentum.

McCALL ANDERSON.

Carbolic Acid in the Treatment of Bubo.—Wolff uses pure carbolic acid liquefied by the addition of one-tenth by weight of rectified spirit, for the treatment of bubo. If non-suppurating he applies every day a layer to the central part over one square centimeter. He ceases these applications when the skin desquamates, and begins afresh a few days later, unless the bubo has disappeared. When the bubo contains pus, the latter is evacuated, and the pocket is touched with the carbolic preparation every two days until granulation takes place, when a simple iodoform dressing is applied.—*Medical Press.*

A Nerve Tonic.—Goodell recommends the following in conditions of nervous exhaustion:

℞ Extract of sumbul,
Sulphate of iron of each gr. xx
Asafetida gr. x
Arsenous acid gr. ss

M. et fiant pilulæ xx. Sig.: One pill after meals three times a day.—Hare's "Practical Therapeutics."

Constipation.—

℞ Aloes,
Sodium chlorate āā gr. xv
Cocoa butter q.s.

M. Sig.: For one suppository, to be taken at bedtime.

METHOD AND ORGANIZATION OF REEDUCATION FOR WAR CRIPPLES IN GERMANY.*

By DOUGLAS C. McMURTRIE,

NEW YORK.

DIRECTOR, RED CROSS INSTITUTE FOR CRIPPLED AND DISABLED MEN; PRESIDENT, FEDERATION OF ASSOCIATIONS FOR CRIPPLES; EDITOR, AMERICAN JOURNAL OF CARE FOR CRIPPLES.

THERE is no general uniform system of care for war cripples in Germany. There is no central authority giving general direction to the work; the reeducation schools for cripples are of varying types and most unevenly distributed. At the same time, the work is of a purely volunteer character; the matter of reeducation is wholly in private hands and is not even supervised by the Imperial Government.

However, in spite of this lack of system and of government control, the work that is being done ranks extremely high, both with regard to its volume and to the efficiency of the individual institutions. This has been made possible by the highly developed system of private charity in Germany and by the existence of a strong body of enlightened public opinion with regard to what constitutes the duty of the nation towards the war cripple.

At the beginning of the war, there was in Germany the usual outbreak of charity, misguided by the traditional attitude towards the war cripple, which was a combination of hero worship with pity for an assumedly helpless member of society. The newspapers were loud in their demands for *Heldenheime* (Old Soldiers' Homes), where all cripples could be maintained in idleness for the rest of their lives. Public sympathy towards the war cripples was in danger of being absorbed in the traditional undesirable forms of charity, to the total disregard of constructive forms of assistance.

Immediately, however, an educational campaign was started to divert public opinion to an interest in the work of rehabilitation and reeducation of cripples. This public education on the subject of proper treatment for war cripples has been very efficient and effective. At the present time, German public opinion has fully assimilated the idea that the real public duty towards the cripple is to restore him to work and to an active participation in the economic life of the country, and that this is a part of the patriotic duty. The faith in the possibility of the rehabilitation of war cripples has be-

come a part of the patriotic faith. The principle that no one need be a cripple unless he himself wishes it, and that "the wounded man must sink back into the mass of the people as though nothing has happened," is accepted as a creed.

These results are due to the work that had been done in Germany before the war for the care of cripples and the achievements that had been obtained. For many years it had been the creed of leading German orthopedists that almost any cripple could be made fit to work again and that education for work should be the regular treatment. Germany was the country which, of all others, had, when the war broke out, the most foundation for caring for cripples. The German Federation for the Care of Cripples (*Vereinigung für Krüppelfürsorge*) was an organization of old standing. There had been developed, during fifty years' experience, fifty-four cripple homes, ranging in size from six to three hundred beds. Some of them were already taking adults as well as children; they had among them two hundred and twenty-one workshops, teaching fifty-one trades. On the other hand, the German system of social insurance was to a large extent responsible for the promotion of the study of the care and training of cripples. Under the insurance laws, a workman is taken care of, for the first twenty-six weeks of illness, by the *Krankenkassen*, which are supported by joint contributions of employers and employees. After twenty-six weeks, he is supported by the *Berufsgenossenschaften* (Employers' accident insurance associations). These latter associations, which have charge of the men for longer periods and are more concerned with cripples than with mere cases of sickness, have made a special study of the physical and mental training of the industrially disabled. Preparing a man to resume his trade was to their advantage, since it relieved them of the necessity of paying him a permanent pension.

When the war broke out, the German orthopedists naturally became the leaders in educating public opinion and took the initiative in organizing the volunteer work for the care of cripples. The first place in this work belongs to the Federation for Care of Cripples, and especially to its secretary, Dr. Konrad Biesalski, Germany's leading orthopedist. Immediately after the outbreak of the war, the Kaiserin, at Dr. Biesalski's suggestion, sent a telegram to the Federation, asking that the German cripple homes throw open their doors to war cripples. To this, all the homes immediately consented. Dr. Biesalski undertook a tour of Germany under the auspices of the Red Cross, in which he visited all the principal cities, urging the formation of voluntary committees for the care of war cripples.

*Detail research work on which this article is based performed by Miss Ruth Underhill of the staff of the Red Cross Institute for Crippled and Disabled Men.

The immediate result was the formation of volunteer committees in many cities and of larger ones in some states and provinces and the starting of work in all parts of the empire under various auspices and with various plans.

While the methods used in the different localities and institutions may greatly vary, there is a complete unity of purpose. Germany has a complete definite scheme as to what constitutes the reconstruction of war cripples. It is accepted by all the institutions working to this end, it is put in practice, and the statement is that in ninety per cent. of the cases the desired results are obtained. The scheme, as expressed by Dr. Biesalski, is as follows:

1. No charity, but work for the war cripple.
2. Cripples must be returned to their homes and to their former conditions; as far as possible to their former employment.
3. Cripples must be distributed among the mass of the people as though nothing had happened.
4. There is no such thing as being crippled, while there exists the iron will to overcome the handicap.
5. There must be the fullest publicity on this subject, first of all among the cripples themselves.

There are four stages in the treatment of war cripples: (1) medical treatment, (2) provision of artificial limbs and functional reeducation, (3) vocational reeducation and vocational advice, (4) placement. These activities are cut sharply in half, the first two being the function of the Imperial Government and the last two of private and state agencies.

All hospitals where wounded soldiers are treated, whether for first surgical care, or later convalescent care, are under military control and discipline. The hospitals are of two types: on the one hand, the regular military reserve hospitals, and on the other hand, the so-called *Vereinigungslazaretten* (affiliated hospitals), or private hospitals which have put at the disposal of the war department either their whole plant, or a certain number of beds.

The *Vereinslazaretten* include all the cripple homes and hospitals which were offered to the war department by the Federation for Care of Cripples, by the *Krankenkassen* and *Berufsgenossenschaften*, by the Red Cross, by many municipalities, individuals and charitable institutions. There is a fairly complete network of orthopedic homes distributed all over the empire, to which men can be sent for final intensive treatment. According to a statement by Dr. Leo Mayer, there are at present about two hundred such institutions, and Germany's facilities for giving orthopedic treatment to crippled soldiers are quite adequate.

The organization of the work, in the stages that are not under the control of the Imperial Government, varies greatly with the different parts of the empire. It is either financed and directed entirely by the state government, as in Bavaria; or it is initiated and directed by the government, but with private cooperation and support; or, finally, it is initiated and financed by private agencies, but with government cooperation. In spite of all these differences, however, there are, in all the divisions of the empire, local care committees for war cripples in almost every town. In all the committees, the agencies represented are usually the same: the

municipality the *Bezirkskommando* (military district command), the accident insurance associations, the Red Cross, the women's clubs, the employers, different business organizations, and the labor unions. Germany is now thoroughly covered with a network of local organizations. In September, 1915, a national committee (*Reichsausschuss*) was elected, at a meeting of representatives of the cripple work from all parts of the empire, for the purpose of coordinating the work of the local organizations.

The wounded soldier, after receiving the first surgical treatment at the field hospital, is removed to the rear: if he needs orthopedic treatment, to one of the orthopedic hospitals. An effort is always made to send men for treatment to their home town. After his discharge from the hospital, the man goes back to his reserve battalion, which is likewise quartered at his home town, and there he awaits the final decision upon his pension and his dismissal as *dienstunfähig*, or unfit for service.

Most of the civilian activities, both in reeducation and in placement, take place while the man is under the authority of hospital or reserve battalion. This makes necessary the closest cooperation between military and civilian authorities. The effect is that of two interlocking systems functioning side by side, occasionally overlapping, occasionally failing to make perfect connections, but, as a rule because they are not really different in spirit, managing very effectively.

Medical Treatment.—The principle upon which the orthopedic treatment proceeds is that practically every cripple can be made fit to work again. This attitude is assumed by all the German writers, in contrast to the French, who make more conservative estimates. It appears to be a definite public policy to assume as an article of faith that rehabilitation is an absolute success and that discussion is superfluous. Dr. Biesalski states that from ninety to ninety-five per cent. of all war cripples treated are returned to industrial life. The time of treatment for a man in the orthopedic hospital is from two to six months. Men are kept here until they are ready to go back to the army or pronounced definitely *dienstunfähig*, unfit for service. Even if they are so unfit, the War Department does not discharge them until they are pronounced by the physician physically fit to go back to civil life.

There is great enthusiasm in Germany over the advances made in orthopedic treatment, and it is certain that the best hospitals are excellently equipped. The arrangements at Nürnberg, for instance, include an operating room, a room for making plaster casts, an x-ray machine, hot and cold baths, massage, electric and medico-mechanical treatments of all sorts. More and more emphasis is being laid on physical exercise as a means of strengthening the stump and also the remaining limbs and of bringing the physical condition back to the standard. The plan is that a man shall begin very simple but systematic physical exercises even before he is out of bed. These are gradually increased until finally he has two or three hours a day under a regular gymnasium instructor. In many places, physical directors from public schools and universities have volunteered their services as instructors. *Turnvereine*, or athletic clubs, often

turn over to the cripples their gymnasiums or athletic fields. Municipalities often place at the disposal of the hospitals their public parks and swimming pools.

Games and outdoor sports are found to have an immense therapeutic value, both psychological and physical, as compared with medico-mechanical treatment. At Munich, at the Königliche Universitäts-Poliklinik and the Medico-Mechanisches Ambulatorium, 2,000 men receive regular physical training. The Oscar-Helene Heim, Berlin-Zehlendorf, reports as part of its regular training for one-armed and one-legged men, ball playing, spear throwing, bowling, shooting, and quoits. The sports at Ettlingen include work on parallel bars for one-armed men and hand ball and jumping for one-legged men, besides regular calisthenic exercises pursued in the open. At the one-armed school at Heidelberg, Dr. Risson reports club swinging for one-legged men, a contest with the horse between the one-armed and one-legged, standing high jump for the one-legged, putting the shot by the one-armed, also ball throwing and hand ball for the latter, the stump being used as well as the good arm. The reserve hospital at Görden, Brandenburg, emphasizes long distance running and takes its men for long hikes in the open in regular running costume. Swimming is also being emphasized. In Berlin, cripples have been given free entrance tickets to the public swimming pools. Their swimming is supervised and no one is allowed to go into deep water until the instructor is sure of his ability. On a day when forty cripples, mostly with arm and leg injuries, made their first attempt, all of them were able to swim without help. In many places, hospital contests are organized or permanent athletic clubs for cripples are created.

Trade training is under civilian auspices and is not conducted directly by the hospitals. Many hospitals, however, have a workshop or two attached for purposes of functional reeducation. There is great emphasis, in all the reports on the subject, on the fact that even this occupational therapy should be really useful and should lead the patient direct to some practical occupation. There is also some emphasis on the fact that a man should be visited and his mind turned toward work at the earliest possible moment before mental lethargy has any chance to set in.

Artificial Limbs.—All artificial limbs are furnished and kept in repair by the government. The government has prescribed maximum prices for prostheses of different types. Otherwise there is no official supervision; no standard pattern is prescribed, and the matter is left to the doctors and engineers of the country.

The result is an immense stimulation of activity. The magazines are full of descriptions of new prostheses recommended by doctors and manual training teachers from all parts of the country. At an exhibition of artificial limbs, held at Charlottenburg, there were shown thirty kinds of artificial arms and fifty legs in actual use. The German Orthopedic Society has devoted much discussion to the matter and there has been wide education and publicity.

The principle now thoroughly accepted is that the prosthesis should reproduce not the lost limb, but the lost function. It should not be an imitation

arm or leg, but a tool. The standard of merit is the number of activities it makes possible. The prostheses usually supplied to cripples answer this definition. The legs are very like the old-fashioned peg leg; the arms are some variation of jointed rod with an arrangement by which different appliances may be fastened to it. With the arm, is supplied a wooden hand covered with a glove which may be attached for street wear. The so-called *Sonntagsarm* (Sunday arm) is never supplied except on request to clerical workers.

The limbs are made by private firms, many of whom sell them at cost price as a patriotic measure. Some of the hospitals have an orthopedic workshop as part of their vocational training equipment, and these make their own limbs or at least prostheses for temporary wear. But there are certain well-known makes of limb which have come into very general use.

The Jagenberg Arm. This is the invention of a factory owner at Düsseldorf, where there is a very large school for the wounded. It consists of two metal rods joined by a ball and socket joint which can be turned in any direction, a grip of the well hand sufficing to fix or loosen it. It is fastened to the stump by a tight-fitting leather cuff. With the arm is furnished a set of twenty attachments suitable for all the ordinary operations of life, such as eating, dressing, etc., and a wooden hand for street wear. The number of attachments can be added at will to suit any trade. The arm is easily made and its parts can be had at any factory.

Rota Arm. Made at the Rota Works, Aachen, after designs by the engineer Felix Meyer. Very similar to the Jagenberg arm, it differs in the manner of attaching tools. A set of attachments and an artificial hand is also furnished with this arm.

Schüsse-Schückert Arm. Made by the Siemens-Schückert Works, Nürnberg, after designs by Dr. Silberstein, of the Royal Reserve Hospital, Nürnberg. The firm manufactures the arm at cost. This differs from the Jagenberg and Rota arms in having the weight of the arm borne by a strap over the shoulder while in the two former the weight comes on the stump. The arm has been tried out, particularly in the Nürnberg carpentry shops with great success. It has a carefully worked-out set of attachments fitted especially for carpentering.

Riedinger Arm. The invention of Professor Riedinger, Würzburg, it consists of a long leather upper arm and short metal lower arm, with a tube into which attachments can be screwed. It is fastened on by a complicated harness over the shoulder and is particularly good for heavy lifting.

Brandt Arm. The invention of Wilhelm Brandt, Brunswick. This is a celluloid arm with sliding joint, meant for lighter work.

Hanover Arm. Made by the firm of Nicolai, Hanover. Here the ball joint is replaced by a hinge, fastened at any angle by wing screws. This arm has also a set of attachments. It is light and particularly suited to clerical workers.

The two *Schönheits* or *Sonntags* arms (decorative arms), made are the Schüsse arm, Leipzig, and Carnes arm, an American patent purchased by a German firm. The Schüsse arm is a perfect imitation of the human arm entirely useless and pur-

chased only by wealthy cripples as an extra prosthesis. The Carnes arm is also an imitation, but with a very complicated mechanism, by which most of the operations of daily life can be managed. The Carnes arm is too expensive and fragile for wide use. A cheap imitation of the Carnes arm has been invented by Professor Bade, Hanover, but is not durable. Even this has not met with wide approval, because the arms made on the tool plan far surpass it in working usefulness.

Two hand prostheses are in wide use, both invented by cripples and both on the principle of the claw. The hand best suited to factory workers is that invented by the locksmith Matthias Natus. It consists of an iron claw fastened with straps to the stump. It grasps a tool like a hand and can then be clamped in that position.

The Keller claw was invented by a farmer, August Keller, and consists of three wires the thickness of a lead pencil wound together claw shape and fastened to the stump by a strap. It grasps tools as does the Natus hand, and its owner has found it entirely successful for all farm operations. It has now been patented and is being widely copied.

The makes of artificial leg have not been so standardized. The general principle on which they are made is that of simple construction and swift repair. Orthopedists have given up the effort to get much foot movement and the usual plan is an unjointed foot with a convex sole. The most noteworthy improvement is that adopted at Freiberg of reducing the weight by making the upper leg of a thin metal rod. The shape of the leg is retained by covering the rod with a wire form covered with elastic. Dr. Alfred Jaks, of Chemitz, has invented a leg consisting of parallel levers which are set in motion by raising and lowering the stump.

In February, 1916, the Society of German Engineers made an attempt to standardize the various efforts in the production of prostheses, by offering three prizes for the best artificial arm. The prize entries were on view for three months with very good educational results. The Society then decided to establish a permanent *Prüfungsstelle* (test station) for artificial limbs, which was opened at Charlottenburg, in February, 1916. The station has been empowered by the military authorities of the Berlin district to advise all cripples of the district as to prostheses. To August, 1916, three hundred and forty-five cripples had been so advised. The Kaiser, from sums placed at his disposal for war relief, has recently turned over 50,000 marks to be used for the purchase and testing of artificial limbs. Twenty thousand of this goes to the *Prüfungsstelle* in Charlottenburg.

Vocational Advice and Reeducation.—Reeducation in Germany goes on at the same time as the medical treatment. This has two causes: First, there is the strong conviction among all cripple welfare workers that results can be obtained only by getting hold of a patient at the earliest possible moment of convalescence, and second, the fact that, since the Imperial Government does not pay anything towards reeducation, it is more economical for the care committees to attend to it while the men are in the hospitals and thus save themselves the expense of maintenance.

The first civilian function in the care of the war cripples is vocational advice. The local care committee usually appoints vocational advisers, which appointments have to be sanctioned by the local military authorities, who control the visits made to the men at the hospitals. As soon as the man is well enough to be visited, the committee sends to him its representative to get full facts on his experience and his physical condition and then advise him as to reeducation or immediate work. The principle is fast held to that a man must, if humanly possible, go back to his old trade, or, failing that, to an allied one.

The trade training is given while the men are still in the military hospital, beginning, in fact, as soon as they are able to be out of bed. The workshops are maintained by the local care committees; they can either be located in the hospital or in a separate building to which the men are transferred every day. The first plan is followed mainly in the case of a few of the larger cripple homes, such as the big hospitals at Nürnberg, Munich, Marfeld, Görden. In most instances, there are no workshops maintained at the hospitals. The local care committee may utilize the local trade schools. There are excellent facilities for this, since every town has at least one trade school. Some representative of the educational authorities generally serves on the local care committee and the schools are eager, in any case to offer free instruction. German magazines are full of advertisements of free courses for war cripples, offered by schools of the most varying kind, public and private, from agricultural and commercial schools to professional schools and universities. On the other hand, in a large town, with a large number of hospitals, the committee may create a school of its own. Thus, in Düsseldorf, for instance, where there are fifty hospitals, the committee has taken possession of a school building equipped with shops and tools and gives twenty courses open to men from all the hospitals.

The instruction offered and the trades taught present a great variety. Thus, at the Nürnberg school, the curriculum is as follows:

A. Theoretic work: left-handed writing, improved writing with right hand, typewriting, stenography, commercial course, general course, for industrial workers, farm bookkeeping, theoretic courses, for the building trades (carpenters, locksmiths, masons, plasterers, etc.), decoration and design, theoretic course for machinists, left-handed drawing, office management.

B. Practical work: tailoring, painting, bookbinding, printing, locksmithing, shoemaking, saddlery, weaving, orthopedic mechanics, machine tool work, carpentry, farming, paper hanging, toymaking, blacksmithing, brushmaking.

The Düsseldorf school offers the following curriculum:

A. General Education: civics, German, manual training, education of one-armed and left-handed men.

B. Theoretic Trade Courses: building trades, metal-working trades (courses for machinists and for draughtsmen), commercial course, course for railway and postal employees and lower position in civil service (office work, telegraphy), course for store clerks, agricultural course, course in handi-

craft as preparation for journeyman's and master tests.

C. Practical Trade Courses with Shop Work: electrical work, metal work, carpentry and cabinet work, locksmithing, stone masonry and carving, graphic trades (printing, lithography, etc.), book-binding, cardboard and leather work, painting and plastering, upholstery and decorating, dental laboratory work.

It is planned that none of the courses shall take more than six months, the maximum time for hospital care. These short courses are intended for men of experience who need further practice in their old trade or in an allied one. If a man needs further training after this short course, he becomes the charge of the local care committee, which supports him in a technical school or pays the premium for apprenticing him to a master workman.

A special effort is being made to return to the land all those who have any connection with it, such as farmers, farm laborers and even handworkers of country birth. All the hospitals which have any land give courses in farming and gardening for their inmates. It is estimated that there are several hundred such hospital farms, small or large, run by the wounded. In addition to this, there are definite summer farm courses at agricultural schools and universities, which are free to cripples. There are in the empire ten regular agricultural schools for war cripples.

Since the one-armed man has the greatest handicap, special arrangements for the training of one-armed have been made in many places. A school for the one-armed means, as a rule, special courses for one-armed men given in the regular city schools where the men will afterward be taught a trade. The purpose of these courses is to exercise the stump and the remaining members, until the man is able to take up trade-training besides others less seriously crippled. The course includes instruction in the ordinary acts of life, such as eating, washing, dressing, tying knots, using simple tools, left-hand writing, etc. In addition all the schools put great emphasis on physical training. Six weeks is said to be enough to put a one-armed man in condition to go on with regular training.

Placement.—There is no uniform machinery for the placement of war cripples. The principle is universally recognized that a "man must go back to his former position." The care committees, while interviewing the man in the hospital, get also in touch with his former employer. Sometimes a position is thus secured even before the man has started on his training, and the latter is then adapted to the requirements of that particular position. It is, however, not always possible to place a man with his old employer. Some of the larger care committees run employment bureaus of their own. Others turn over the man who cannot be taken back to his old position to another agency, mainly to the employment bureaus. Germany has a regular system of public employment bureaus supported by the municipalities. The bureaus in each state or province are united under a state or provincial directorate, and the directorates in an imperial federation. Some of these bureaus had, before the war, special divisions for the handicapped, and others are now forming them.

Employers' and workmen's associations are of considerable assistance in the placement of war cripples, especially the *Vereinigung Deutscher Arbeitersgeverbände*, (Federation of German Employers' Associations), which has been recently formed for this particular purpose, and the many master guilds of handworkers. There are also a number of agencies due to charitable or private initiative.

Finally, there are open to war cripples a very large number of positions in government service. The Imperial Government has promised that all former employees of the railways, post office and civil service will be reemployed, if not in their old capacity, in a kindred position. These men are to be paid without consideration of their pensions. The post office department has decided to give all future agencies and sub-agencies in the rural districts to war cripples, provided they are fit for the positions and want to settle on the land. Many city governments make efforts to take in cripples. A number of employments under the war department are reserved for cripples. The war department, through its recently created welfare department (*Versorgungsabteilung*), attempts also to develop a placement activity wherever there is no very active local care committee, and publishes twice a week a journal which gives the positions open for war cripples.

FURTHER EXPERIENCES WITH THE DIRECT EXAMINATION OF THE DUODENAL CONTENTS IN AFFECTIONS OF THE GALL-BLADDER AND ALLIED ORGANS.*

BY MAX EINHORN, M.D.

NEW YORK

PROFESSOR OF INTERNAL MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL

THE utility of the direct examination of the duodenal contents (bile and pancreatic secretions) in affections of the liver, gall-bladder, and pancreas is so self-evident that it hardly appears necessary to discuss it. The fluids of all accessible cavities are eagerly studied (gastric contents, feces, urine, blood, spinal fluid) and their characteristics found useful in establishing a diagnosis. Why should not this be done with the duodenal contents? The latter, as it is well known, carry with them secretions and excretions of vital import for the existence of the organism (duodenal and pancreatic juices and bile). It is but natural that affections of the liver, gall-bladder, and pancreas will gain considerably in clearness by frequent and thorough explorations of the duodenal contents.

In two previous papers^{1,2} I have published the results of my findings in this respect. In the present article I intend to report my new experi-

*Read before the American Gastro-Enterological Association, May, 1918, at Atlantic City, N. J.

1. Max Einhorn: Direct Examination of the Duodenal Contents as an Aid in the Diagnosis of Gall-bladder and Pancreatic Affection, *Amer. Jour. Med. Sciences*, Oct. 1914.

2. Max Einhorn: The Duodenal Tube as a Factor in the Diagnosis and Treatment of Gallbladder Disease. *J. A. M. A.*, June 19, 1915.

ences with the direct examination of the duodenal contents in affections of the gall-bladder and allied organs. For the sake of brevity I shall describe all the cases in which the direct examination of the duodenal contents was of material aid in diagnosis in the subjoined table, while a few of them will be sketched in greater detail. The latter are as follows:

CASE 1.—Gastric ulcer and cholecystitis, February 2, 1918 (Table No. 11). Mrs. J. T. P. had a sudden attack of pains in the epigastrium and slight jaundice, requiring morphine, one and one-half years ago. These attacks of gas and distress in the stomach occurred after getting tired or overeating about once a month, later oftener. Patient also suffered from constipation and slight pains relieved by bicarbonate of soda. On January 10 the patient had a severe attack, requiring a hypodermic, lasting two days. Since then there was a temperature of 100° to 101° up to February 7. Patient felt weak and had lost 17 pounds in weight.

Present condition: Patient looks somewhat pale. There is nothing abnormal to be elicited in the chest organs. The stomach extends one to two fingers' breadth below the navel. The epigastrium is painful to pressure. The liver is not enlarged.

Examination of the gastric contents one hour after a test breakfast shows: HCL +; Acidity = 65. Duodenal bucket (February 9, 1918) passes the pylorus and shows a blood stain at 41-42 cm., bile 55 cm. down to the end. The examination of the duodenal contents, fasting condition, shows as follows: yellow, very turbid, alkalinity = 40; A = 20; S = 7; T = 4.5. The blood count is as follows: red blood cells = 6,000,000; Hb = 100 per cent.; white blood cells = 8,000; polymorphonuclears = 68 per cent. The blood pressure is 128 mm. The urine does not show any albumin or sugar or bile. The temperature is: morning, 99°; evening, 100.5°. X-ray examination by Dr. Stewart revealed a pathological gall-bladder with adhesions and marked prepyloric spasm.

The diagnosis was gastric ulcer and cholecystitis, probably due to gallstones. Patient was treated by duodenal alimentation and instillation into the duodenum every other day of 15 c.c. of either a one-half per cent. argyrol solution or a one per cent. ichthyol solution. After a few days' treatment the temperature was normal, and the patient felt better. The duodenal contents began to look better (less turbid).

CASE II.—Mrs. R. K., November 1, 1917. Cholelithiasis (Table No. 6). Patient was well until four years ago, when she began to be troubled with pain in the stomach 2-3 hours after eating. These attacks would occur once or twice a month for several days and last one-half hour. Six months later the condition became worse. The attacks occurred more often and were more severe. The pains appeared 5 or 6 hours after eating and would spread over the entire stomach. Vomiting would bring relief. This condition has become steadily worse up to the present time, the patient having lost 40 pounds during the past six months.

Present condition: Two to three hours after eating patient complains of severe pain in the stomach. These pains continue until the stomach is emptied by vomiting, which is usually 4 to 6 hours after meals. The attack of vomiting lasts about 1 or 2 hours, after which the patient is very weak and complains of muscular pains all over the body followed by chills. The latter condition lasts about one hour. The patient looks slightly icteric. The thoracic organs do not reveal anything abnormal. The stomach is slightly dilated extending to two fingers' breadth below the navel. The liver is slightly swollen, overlapping one finger's breadth the margin of the ribs in the right mammillary line.

Examination of the gastric contents revealed the following: HCL = 0; acidity = 30; no blood. The duodenal bucket string was 65 cm. in length; bile 35-65 cm.; blood stain, 49-51 cm. The duodenal contents on November 1, 1917 (fasting condition) were yellowish brown, twice the normal amount; alkalinity = 20; A = 10; S = 4; T = 6. On November 5 the duodenal contents were yellowish green and turbid. A = 10; S = 5; T = 3.

The blood count: red blood cells = 3,200,000; Hb. = 85 per cent.; white blood cells = 8,000; polymorphonuclears = 79 per cent.

The diagnosis of gallstones was made and an operation recommended. Dr. Willy Meyer performed the operation. A number of hazelnut-sized stones were found in the gall-bladder and two were discovered lodged in the common duct. Cholecystectomy was done and the patient made a perfect recovery.

CASE III.—Mrs. K. S. Chronic pancreatitis and jaundice due to pressure on the common duct. October 1, 1916. For the last five years the patient complained of severe diarrhea, epigastric distress, weakness, and loss of weight. Patient looks pale and thin; tongue not coated. Chest organs are apparently normal. The stomach extends to about one finger's breadth below the navel (splashing sound). The liver is not enlarged. The examination of the gastric contents one hour after a test breakfast shows as follows: HCL = 0; Acidity = 4; no rennet; very little fluid; pieces of roll not changed; no blood. The bead test revealed that the beads appeared in the stool after 42 hours, with fish-bone, catgut, fat, meat, and thymus containing nuclei, present.

On October 7, the patient had pains in the right upper abdomen, felt chilly and became slightly jaundiced. The duodenal contents were examined on October 12, in the fasting condition, with the following result: watery, no bile, alkalinity = 10; A = 2; S = 1; T = trace.

The diagnosis of chronic pancreatitis and probably also gallstone colic was made. In view of the fever which was continuous and symptoms of cholangitis, an operation was recommended. On October 19, 1916, the patient was operated by Dr. Willy Meyer. No stones were found in the gall-bladder; the pancreas was thickened and hardened; the glands in the neighborhood swollen. An appendectomy and cholecystostomy were performed. Patient made a good recovery. The bile running from the fistula examined on October 24, showed: A = 2; S = 0; T = 0; Alkalinity = 40. The draining of the gall-bladder was kept up for a number of weeks and had a remarkably good effect on the general condition of the patient. She has picked up in weight; diarrhea has disappeared, and the patient remains pretty well up to date (March, 1918.)

CASE IV.—Carcinoma of the stomach and pancreas. (Table No. 20.) Mrs. R. October, 1916. The patient complained of gastric disturbances for about ten weeks before consulting me. The chief complaints were pains one hour after meals, loss of appetite, and a loss of fourteen pounds in weight. The gastric contents showed: HCL + Acidity = 74; occult blood present; no food retention. The string test showed a blood stain at nineteen inches from the lips and bile below 23 inches, showing permeability of the pylorus. A resistant mass was palpable below the left costal margin. Examination of the duodenal contents as follows: clear, yellow (golden); alkalinity = 20; A = 3; S = 2; T = 0. A diagnosis of carcinoma of the stomach (lesser curvature), probably involving the pancreas was made.

As the patient was quite young, about 38 years, an operation was decided upon, in order to attempt to bring relief if in any way feasible. The incision, however, showed a considerable malignant tumor of the lesser curvature of the stomach extending to and involving the pancreas. The pylorus was free. The mass was left intact and the wound closed.

Two or three weeks after the operation the pains were excessive and the patient could not take the least food without suffering greatly. In order to bring some relief and help nutrition, duodenal alimentation was instituted. The food entering the duodenum, not touching the stomach, thus leaving the tumor unmolested, proved to be a great boon to the patient. She rallied considerably and felt pretty well for a while. In resuming the ordinary way of alimentation the pains returned and opiates were constantly required to reduce the suffering and make the condition bearable. A few months later the patient asked for a new period of duodenal alimentation which was given her again with some benefit. The patient continued to live and to suffer until nothing was practically left of her body, excepting skin and bones and then she died.

SPECIMENS OF NORMAL AND ABNORMAL DUODENAL CONTENTS

1. Mrs. M., Cholecystitis, Oct. 13, 1917. Dark yellowish brown.
2. Mrs. P., Cholelithiasis, March 9, 1916. Golden yellow, turbid.
3. Mrs. S., Cholelithiasis, Feb. 28, 1916. Brownish purple, turbid.
4. Mrs. N., Normal, Feb. 25, 1918. Golden yellow, clear.
5. Mrs. W., Pancreatitis, March 6, 1916. Purple, clear.
6. Mrs. J. H. McE., Nov. 24, 1917. Dark green, yellow tinge, slightly turbid.
7. J., Cholecystitis, ulcer duodeni, April 19, 1916. Dark brown, tinged with yellow.
8. Mrs. R., Cholelithiasis, Feb. 15, 1914. Greenish, turbid.

In this case it was of special interest to watch the function of the pancreas which was frequently tested. We give here the different examinations which always showed an entire absence of the trypsin ferment. The examinations were as follows:

Oct. 21, 1916. Alkalinity = 20; A = 3; S = 2; T = 0.

Oct. 23, 1916. Alkalinity = 5; A = 3; S = 2; T = 0.

Oct. 27, 1916. Alkalinity = 30; A = 4; S = 5; T = 0.

March 6, 1917. Alkalinity —; A = 0; S = trace; T = 0.

CASE V.—Duodenal ulcer with periduodenal abscess. January 13, 1917. (Table No. 22.) Mr. J. F. D., about forty-six years old, was troubled for a number of years with pains in the upper abdomen late after meals covering periods of 4 to 6 weeks, intermingled with intervals of perfect euphoria lasting 6 or 8 months. For the last 4 weeks patient has been suffering from a similar attack of pains in the abdomen. In addition to the old symptoms patient experienced great weakness and had off and on chilly sensations, accompanied by a slight rise of temperature.

Present condition. Face is flushed; tongue is coated; chest organs apparently normal. In the abdomen there is tenderness to pressure over the epigastric region. The liver dullness is increased upward up to one finger

below the right mammilla and downward two fingers below the costal margin. At the lower margin of the liver a resistant mass can be palpated three inches in length and one and one half inches in thickness. The gastric contents showed HCl + Acidity = 74; no blood; the stool blood negative. The Wassermann was negative. The thread test showed a blood stain from 23 to 23½ inches, and bile below 24 inches. The duodenal contents were as follows: golden yellow, clear; alkalinity = 20; A = 8; S = 3; T = 3. The blood was: Red blood cells = 5,300,000; Hb. = 88 per cent.; White blood cells = 13,760; Polymorphonuclears 79 per cent. This examination was made on January 23, 1917. On the 24th the blood was: whites = 14,000; polymorphonuclears = 80. The temperature fluctuated between 99° and 102° F. and was of an irregular type. The x-ray examination did not show anything definite. The urine revealed the absence of albumin and sugar and the presence of urobilinogen.

With regard to the diagnosis the past history and the thread test pointed to a duodenal ulcer. While the present symptoms and the swollen liver with the rise of temperature and the considerable leucocytosis seemed to indicate an infection process probably due to some gall-bladder disease. The clear golden yellow bile appeared to negative an infectious process in the gallducts. The resistant mass beneath the liver and the

TABLE OF CASES IN WHICH THE EXAMINATION OF THE DUODENAL CONTENTS WAS OF DIAGNOSTIC AID (MAY, 1916-MARCH, 1918)

Case	Name	Diagnosis.	Date.	EXAMINATION OF DUODENAL CONTENTS.				Appearance of Duodenal Contents.	Remarks.
				Alkalinity.	Amylopsin, Mm.	Steapsin, Mm.	Trypsin, Mm.		
1	Mrs. B.	Cholecystitis and probable cholelithiasis.	5-24-16	10	6	..	3	Greyish, tinged with yellow (straw color), turbid, mucous.	Rennet +. At operation stone found in common duct.
2	Mrs. L.	Cholelithiasis.	6-15-16	10	1½	..	½	Slightly turbid, yellow, mucous.	Operation. Gallstones found.
3	Mrs. T. K.	Cholecystitis.	6-16-16	20	5	1	3	Yellow, turbid.	X-ray=circular shadow, probably due to gallstones, operation for adhesions over cecum; gallbladder contained no stones.
			6-19-16	30	8	2	3	Purple, clear.	
4	Mrs. B.	Cholelithiasis.	3-2-17		8	Trace	..	Whitish, turbid, trace of yellow.	Operation. Gallstones found.
5	Mrs. B. H.	Cholelithiasis.	4-20-17	30		..	..	Yellow, turbid.	Milk unboiled=coagulated Milk boiled=no coagulation Operated upon by Dr. Willy Meyer Gallbladder enlarged, containing seropurulent fluid and stones (cholecystectomy).
			4-24-17		4	1	3	Yellow, clear.	
6	Mrs. K.	Cholelithiasis.	11-1-17	20	10	4	6	Yellowish, brown, twice normal amount.	Gallstones found at operation. Case described in detail.
			11-5-17		10	0.5	3	Yellow, green, turbid.	
7	Mrs. S.	Duodenal ulcer and cholelithiasis.	11-9-17	30	10	4	6	Yellow tinge of green, slightly turbid.	Operation=200 stones found in gallbladder. The duodenal bucket test= blood at 22½ inches. On 11-18-17, rise in temperature and blood count = Polys.=78 per cent.; W. B. C.=10,200.
8	Mrs. A. L. M.	Cholecystitis.	10-11-17 10-13-17	(Gastric contents 20)	=HCl + S	Ac.=40	+	Greenish, brown turbid.	Operation on 10-27-17. No stones found; gallbladder looked like velvet and dark brown. Bile=dark brown resembling Kumbacher beer. X-ray=diagnosis of gallstones.
9	Mrs. J. H. McC.	Cholelithiasis.	11-24-17	20	10	6	4	Dark green with tinge of yellow and slightly turbid.	Operation 11-26-17. Gallstones found in gallbladder and common duct. Blood count=R. B. C.=4,800,000. W. B. C.=11,800. Polys.=8,270. H. B.=90 per cent. Temperature, 99-101 deg. F.
10	Mrs. R. F.	Cholelithiasis.	2-12-17	40	2	2	4	Whitish, no bile.	Operation. Stones found. Cholecystectomy.
11	Mrs. P.	Gastric ulcer; cholecystitis.	11-8-18	40	20	7	4½	Milky, cloudy, no bile.	Case described in detail.
12	Mrs. I. N.	Peptic ulcer; cholecystitis.	6-17-16	30	5	..	½		X-ray=gallbladder disease. No operation.
13	Mr. W. D.	Cholecystitis.	6-27-16	25	7	8	3	Watery, cloudy.	Blood count=W. B. C.=12,000. Polys.=71 per cent.
14	Miss B.	Peptic ulcer; cholecystitis.	10-3-16	30	2	..	..	Light, yellow turbid.	No operation.
15	Mr. W. N.	Cholecystitis.	3-2-17	30	7	2	5	Yellowish, slightly turbid.	No operation.

21	Mr. H. W.	Carcinoma of pancreas.	9-9-16	..	6	..	..	Whitish.	Rennet. Absent.
22	Mr. D.	Duodenal ulcer, with periduodenal abscess.	1-13-17	20	8	3	3	Golden, yellow, clear.	Liver enlarged, case described in detail.
23	Mr. J. K.	Hemolytic jaundice and cirrhosis of liver.	5-15-16	30	3	2	1	Greenish, yellow and turbid.	
24	Mr. A. S.	Hemolytic jaundice and cirrhosis of liver.	3-2-17	30	6	6	4	Yellow, brown, turbid.	

temperature curve in conjunction with the leucocytosis pointed to a suppurative process in the upper abdomen near the liver, requiring surgical aid. The operation performed by Dr. Willy Meyer disclosed a periduodenal abscess. The gall-bladder was found to be normal. About 3 or 4 ounces of pus were evacuated and the wound was drained. The temperature continued for a number of days. The patient being extremely weak and exhausted duodenal alimentation was instituted. Under this regime his strength increased from day to day and the fever disappeared. The patient then made a perfect recovery and regained in a few months the forty pounds he had previously lost.

In looking over the table we find eighteen cases of probable cholecystitis with turbid bile. In ten of these, in which the diagnosis pointed to gall-stones, operations were performed. In eight, stones were found, while in two cases (Mrs. T. K., No. 3, and Mrs. A. L. M., No. 8) no stones were found; in one case, however, the bile aspirated during the operation from the gall-bladder looked dark brown and was turbid, representing exactly the sample, which had been previously obtained by duodenal aspiration. In this case the gall-bladder was excised; the mucosa was found to be inflamed and thickened, representing the strawberry type. In a few of the eight non-operated cases (11-18) the x-ray report likewise seemed to indicate some pathological condition of the gall-bladder. Cases 19 and 20, both representing several pancreatic lesions which came to operation, one benign the other malignant, have been described in detail. They are of interest; in one the trypsin ferment was greatly diminished; in the second it was always entirely absent.

Case 21 is probably one of malignant disease of the pancreas. In Case 22 the bile was clear and seemed to negative gallstone disease. For further particulars see the full case report (Case V).

Another case of clear bile, not mentioned in the table, that came to operation is likewise of interest and helpful in excluding gall-bladder disease. The patient, E. T., had three attacks of severe abdominal colic and gastric hemorrhage in the course of four years. During the last attack there was tenderness over the right abdominal side (gall-bladder and appendicular regions). The thread showed no distinct blood stain, the bile was golden yellow and clear. The diagnosis of appendicitis was made. At the operation the stomach and gall-bladder were thoroughly explored and found normal. The appendix was diseased and strictured. It was removed.

Cases 22 and 23 represent hemolytic jaundice; both were intensely icteric, but bile was constantly found in the duodenum, but was very turbid.

As seen from the table and the few cases described in full the examination of the duodenal contents with regard to the appearance of the bile and the presence and quantity of the pancreatic ferments was often of importance and helpful in making a diagnosis.

In a former paper I described a method of imitating the looks of the duodenal contents in such a way that an imitation sample can be kept as a record. To-day I take pleasure in showing you a colored plate of a number of samples of normal and abnormal duodenal contents (representing principally bile).

You can easily see the great varieties and deviations from the normal encountered in the duodenal contents in pathological conditions. It is principally the changed bile which produces these kaleidoscopic variations. Normally it is clear and golden yellow. In pathological states it is frequently turbid and greenish or dark brown.

The duodenal contents can be examined for a great many other items than those stated in the present table. Thus the bacteriological and the microscopical examinations are of import. A great many other points which I shall not broach here will likewise have to be investigated. Even with the scant knowledge we have at present at our command the study of the duodenal contents (bile and pancreatic juice) is frequently of value in abdominal pathology. The direct examination of the duodenal contents deserves, therefore, to be more frequently employed in the field of internal medicine.

ADIPOSIS TUBEROSA SIMPLEX;

A REPORT OF THREE CASES.

By J. M. ANDERS, M.D., LL.D.,

PHILADELPHIA.

IN 1908 the writer reported four cases, which presented a condition not previously described, to which he gave the name Adiposis Tuberosa Simplex. This disorder occurs only in obese subjects and is more commonly perhaps associated with the anemic than the plethoric form of adiposity. The following excerpt from my original article accurately characterizes the condition met with in the three cases recorded below and also in those previously reported:

"Circumscribed fat masses appear in the subcutaneous tissues; they form distinct, moderately dense, slightly movable, somewhat flattened tumors, ranging in size from a bean to that of a hen's egg. Their number varies all the way from one-half dozen to two dozen or more. These moderately firm fat-nodules are not distributed over the entire body, but in some cases are confined to the extremities, particularly the lower, and in others to the abdomen. The tumor masses show no tendency to fuse together and are not elevated above the surrounding surface; they are sensitive to the touch and may be the seat of pain which varies in intensity within rather wide extremes, being moderately severe and distressing in rare cases and trivial or even absent in the majority of instances.

"The lymphatic glands are not involved, and the skin remains soft, flexible and non-adherent. The mental processes are normally active and also the muscles; asthenia is not present, and there is no more indisposition to physical exertion than is observed in cases of obesity as a rule. The knee-jerks are present and the cutaneous sensibility is unaltered, in some cases, at least."

CASE I.—Miss O. P., aet. 39 years, weight 188 pounds, height 5 feet 3 inches, applied to me for examination and treatment on November 3, 1916. History of obesity in paternal ancestors; also one of two sisters weighs 194 pounds. Father died of cardiorenal disease. One sister has had acute rheumatism. Patient had the usual diseases of childhood; appendicitis

three years, and both sciatica and "intestinal indigestion" two years, since. Menstruation has been "irregular" for several years prior to two years ago, but normal since then. Patient has paid slight attention to her diet in the past and has not taken exercise systematically. She has suffered from headaches daily during the past month, has dyspnea on exertion, is somewhat nervous and irritable. It is probable that the latter symptoms are due to frequent "aching" pains in the region of the appendix. Over the extremities, especially the lower, were to be felt small masses about one-half dozen in either leg, which masses were non-adherent to the skin, not visible, a few slightly sensitive to the touch or palpation and all strictly isolated.

The blood pressure was 122 systolic and 95 diastolic, and physical examination of heart, lungs and abdomen proved negative, if fat-deposits and their mechanical effects be excepted. Repeated examinations of the urine gave a favorable result, although hyperacidity and a marked uratic deposit were almost constantly present.

As the result of suitable treatment, chiefly dietetic, for the obesity, there ensued a gradual loss of weight until 165 pounds was reached at the end of six weeks. With the decline in avoirdupois, the circumscribed fat masses gradually diminished in size and most of them disappeared.

Later, an increase in bodily weight caused one-half dozen small fatty tumors to reappear, several of these being found on the upper arms. Subsequent reduction of the patient's avoirdupois again resulted in a disappearance of the fatty lumps. It is of interest to note that these masses developed within a brief period—three months.

CASE II.—Mrs. P. R. S., aet. 59 years, nativity American, occupation housekeeping, married, weight 222 pounds, height 5 feet 8 inches, first fell under observation May 2, 1910. The family history reveals gout in the paternal grandmother, while the father had died of organic heart disease, although beyond 75 years of age; the father was heavily built, but did not appear fat. Otherwise, the history of ancestors and near relatives was negative. Patient had childhood diseases, and suffered from marked pyrosis during two pregnancies; at time of menopause, which had taken place five years previously, developed "neuritis" in arms and legs. Patient observed small lumps over extremities to palpation; condition had slowly improved since visits to Virginia Hot Springs.

Present Illness: A physical examination revealed on inspection abnormal fat deposits, most marked over thighs, hips and abdomen, while the bones were small. There were fat lumps in the lower limbs somewhat larger than those observed in other cases of this condition; they were somewhat tender to palpation, but did not project above the skin surface; arteries hard to the feel, and nerves of the extremities tender to the touch. The heart sounds were clear though muffled, and the aortic second accentuated. The uranalysis proved negative in its results both chemically and microscopically.

The treatment consisted of massage to hips and abdomen three times weekly, a walk of three miles daily, a glass of Celestine vichy three hours after mealtime and on rising, a tepid sponge bath once daily and the following dietary:

Breakfast: Fruit, as oranges, stewed prunes, or grape fruit; pulled or toasted bread, 1 oz.; a small amount of hominy grits; a soft boiled egg or an egg cooked in any manner except fried; coffee, 4½ oz. (without sugar or cream).

Luncheon: Sweetbread, white meat or fowl or game, 2 to 3 oz.; French rolls or toasted bread, 1 oz.; fruit (except strawberries and bananas); a small amount of fat in the form of butter and cream; water, 6 oz.

Dinner: Clear soup (about 6 tablespoonfuls); fish; white meat of chicken or game, and mutton and veal (occasionally), 3 to 4 oz.; green vegetables, as spinach, string beans, green peas, lettuce, and macaroni stewed in milk, 1½ oz. For dessert, plain rice pudding, junket, or fruit (except strawberries and bananas).

The above method of treatment caused the patient's weight to fall from 222 pounds to 196 pounds in the

course of two months. The general condition was now greatly improved and the fat lumps much diminished in size. Unfortunately, the patient, who lived in another city, passed from observation at this time and, although the miniature tumors had not entirely disappeared, the writer feels confident that further treatment of the kind pursued would have caused their removal in toto.

CASE III.—Mrs. S. H., aet. 37 years, nativity American, first applied to me for treatment October 30, 1910. *Family history* disclosed the fact that her mother and one paternal aunt had been subjects of obesity. Among previous illnesses, typhoid fever at 28 years was the chief; patient grew slowly stouter after recovering from that disease. For example, prior to the occurrence of typhoid fever her weight was 107 pounds, whereas she now weighs 180 pounds. There are no symptoms apart from a feeling of fatigue, especially after exertion. A blood examination shows an anemic type of obesity. In the left hypochondriac region on a line with the left nipple a small, fatty, deep-seated tumor can be felt; this is slightly tender to palpation and freely movable. The uranalysis gave a normal result.

The patient remained under treatment for a period of six months with marked reduction in weight (154 pounds) and felt greatly improved as to her general health. The small fat tumor disappeared as the result of the treatment carried forward for the obesity. A recent visit of this patient to my office for a different complaint (severe cold) gave me an opportunity to inquire with regard to the small fat lump which the patient stated had not recurred.

The cases of obesity in which separate, small, fat-masses occur are, as stated in my former article, quite rare. Their existence, however, is to be recollected. Again, the harmlessness of these localized fat deposits, their etiological connection with obesity, as shown by their disappearance under appropriate treatment for the latter condition, are facts which make it desirable that they should be placed in a special clinical group, so as to avoid confusion of individual cases with adiposis dolorosa on the one hand and nodular circumscribed lipomatosis without symptoms on the other.

To regard the condition merely as an occasional variation in the clinical picture of simple obesity, as Lyon² suggests, fails to emphasize sufficiently its clinical importance and relationships to other conditions in which fat lumps occur.

Price³ speaks of the condition under discussion as standing halfway between simple adiposis and nodular circumscribed lipomatosis with absence of general symptoms. The close clinical association of adiposis tuberosa simplex and instances of the last-named syndrome in which constitutional features are missing, is obvious, since pain is present in rare cases only of the former condition.

The writer, therefore, feels inclined to accept Price's classification for the present. If adiposis tuberosa simplex forms a connecting link between simple obesity and nodular circumscribed lipomata, it would seem wise to designate it by a special grouping. Clinically, adiposis tuberosa simplex does not conform, in certain particulars at least, to the description of simple obesity.

THE HEALTHY SCHOOL CHILD.

SCHENECTADY'S SYSTEM OF KEEPING HIM HEALTHY.

BY WILLIAM J. BOOKS, M.D.,

SCHENECTADY, N. Y.

THE healthy school child constitutes the major educational problem of the public schools. Most children are healthy, and are able to advance according to an established standard, or even exceed the schedule for their age. Therefore, from a purely educational standpoint a thoroughly modern and efficient school system attains its highest efficiency and achieves its best results with healthy children.

An unhealthy child introduces a disturbing factor into the normal progress of a school, a diverting agent from concentrated effort on the normal child. Any distracting feature, as an over-age child in a grade—in the majority of instances due to physical defect and consequent poor health—forces a division of interests and complicates the ordinary difficulties of teaching. Or the long period of absence of a large number of pupils, incident to epidemics, delays an educational program. And while the majority of children are healthy, still many who may be classed as healthy are handicapped by some physical defect or habit or home condition which interferes with their best mental and physical development.

To secure the maximum benefit of public-school education it is obviously essential that the child be healthy; it is equally clear that if the maximum is to be approached, not only must the healthy child be maintained and improved in health, but for the unhealthy child must be secured a condition of good health. Communities, to eliminate a far too great economic waste of human material and educational effort, must provide the necessary force to insure a healthy school child. The cumulative result, stronger men and women, physically and mentally, is not the least reward of such a policy, though mentioned briefly.

Schenectady has recognized the immediate and future value of the healthy school child. For several years previous to 1915 the city maintained a relatively large health organization in connection with its schools, six doctors and six nurses, but with indifferent success, because of lack of coordinate and intelligent effort.

In 1915, in order to secure results, the staff was reorganized, placed under the direction of a chief of staff, and the development of a comprehensive inspection system commenced along scientific lines. In 1918, the staff consists of a chief medical inspector, six school physicians, two dentists, an oculist, and thirteen nurses. This force is engaged in the health supervision of 18,000 school children in twenty-eight public and parochial schools, probably the largest force per 1,000 children maintained by any city.

With the valuable services of a dispensary operated by the Schenectady Day Nursery, every school physician being prominently associated with the dispensary staff, and with a dental dispensary conducted by the public schools, the city is probably the best equipped city in the country for the preservation of the health of its school children. Having assumed the responsibility, Schenectady has met a big problem in a big way.

THE SCHENECTADY SYSTEM.

Nurses.—In the Schenectady system, each of the twenty-eight schools are visited daily by a nurse, the nurse appearing at the opening of the session. On entering a building the nurse notifies the school's telephone operator, and a record is made of her presence. She also notifies the operator when leaving the building. By this simple arrangement the exact location of every nurse is known at all times at the central switchboard, and no delay is experienced in cases of emergency. The presence of the nurse in the building is also signaled to all rooms of the building.

On appearing at the opening of a school session the nurse admits all children who have been absent because of illness, each child receiving a thorough examination to detect signs of contagious disease. After this preliminary work in a school the nurse goes to the next school of her district, and admits the returning children of that school. After this feature of the daily routine is completed, the nurse proceeds to class-room inspections, treatments, sanitary inspections, home visits, etc.

Districts.—Each nurse is assigned to two schools, working alternate mornings and afternoons in each school of her district. A nurse will thus have under her inspection from eight hundred to eighteen hundred children. From a health standpoint this arrangement is all that could be desired, and is indeed a farsighted policy. It may be argued that each nurse could supervise many more children. This holds true—if the children are in districts which can be visited daily by the nurse. A nurse can properly supervise the health of about 3,000 children, on condition that these children are in one or two schools, so that the schools can be visited daily. A nurse cannot properly supervise the health of 3,000 children in three, four, or five schools, so that the schools can be visited only every third or fourth day. This will be demonstrated later on, in a comparison of epidemic conditions of several years ago with present-day conditions. It is also very evident in the great increase of defects found with the more intensive inspection which the enlarged staff has been able to give.

School Physicians.—The school physicians, six in number, spend one hour of work daily in one school of their district. On entering a building the doctor reports to the school telephone operator and also on departure. This eliminates delay in calling the doctor. Each school receives one full hour's work a week, during which time the doctor vaccinates, examines children, or directs treatments, according to the routine of his work.

Another hour is spent daily in answering calls to other schools of his district or making home visits. While each school is visited once weekly, at which time the doctor spends his entire morning's work, he is subject to the calls from other schools of his district at any time during the week.

Two school dentists, and a dental dispensary are included in the health forces of the public schools. The dispensary is operated daily from 9 A. M. to 12 M., each dentist working alternate mornings.

There is one school oculist, with dispensary in the day nursery. Examinations and treatments are conducted on two mornings of each week. A school

fund has been included in the budget for the purchase of glasses, making it possible for a child to obtain glasses when parents cannot afford to buy them.

A *Chief Medical Inspector*, devoting all time during school hours to the work, is the director of the health work in the schools. His duties are administrative, and he formulates the health policy of the inspection force. He has general supervision over the nursing and medical staff, directs control of epidemics, open-air schools, and is head of the mental clinics. His superior is the superintendent of schools.

General Consideration.—(1) Epidemic prevention—contagion control. (2) Vaccination. (3) Physical examinations. (4) Special features.

1. *Epidemic Prevention.*—The educational routine of the Schenectady public schools has not been disturbed by an epidemic of any disease during the two years in which the present system has operated. In considering the epidemic problem it is interesting to compare present-day conditions with the conditions of former years, when the medical inspection system was rather rudimentary.

Measles.—In 1913-14 an epidemic of measles had its inception in November, and lasted throughout the entire school year. About fifty cases appeared in November, 1913, and increased each month in intensity until in March and April, 1914, as many as five or six hundred cases occurred monthly. During the entire school year there were about 1,500 cases of measles in the school system alone. Entire school rooms would be depopulated for a week or two at a time. It requires no great imagination to realize the disorganization this caused in the educational schedule. In order to combat the situation all other work of medical inspection was dropped, and the entire attention of the staff was directed toward the control of the measles epidemic.

If a review of the city health records is made it will be noticed that epidemics occur in waves, each alternate year showing a return of a disease. For instance, scarlet fever will predominate one year, and measles will be the prevalent disease the following year. Therefore, after the measles epidemic of 1913-14 preparations should be made for a recurrence of measles in 1916-17.

Till the Christmas holiday of the 1916-17 school year, under the new system of school inspection, the school system was relatively free of contagious disease. In October, 1916, shortly after the opening of school, a small outbreak of measles occurred, but was segregated to one district and controlled without difficulty. With the exception of a few sporadic cases of measles during November and December, there was no tendency toward another outbreak.

During the holiday vacation, when the children were free from school, a small outbreak occurred in the Bellevue district. Children mingled freely at play, parties, moving-picture houses, and Sunday schools, and the disease was widely scattered in the district. As was natural, foci of contagion were spread to other parts of the city by children visiting back and forth.

When the school reopened after the holidays the nurse discovered eight active cases of measles in school. These cases were the first intimation that measles had become prevalent during the holidays,

as the records of the Health Department disclosed no increase in the number of cases reported by family physicians. This district was immediately placed under very rigid supervision and a general warning issued. During the next two weeks about twenty cases occurred in the school, but under the close inspection and early exclusion and segregation of suspicious cases by the doctor and nurse, the outbreak in this school began to subside. Similar conditions occurred in other parts of town, but under the same thorough inspection the outbreak was handled without any disruption of the educational work.

It is significant to note that the school most affected was a school where the inspection work was disturbed at the most critical time by a breakdown in health of the school nurse, which necessitated her relief from duty. Until this time the situation was under control in the district. Until the new nurse could become acquainted with the district, a matter of a few days, the disease attained increased momentum, and in a short time an entire room was depopulated. Another grade was also seriously affected before control was regained.

The Old and the New Results.—In comparison with the year 1913-14, in the winter of 1916-17 there were not more than one or two hundred cases of measles a month, and it is safe to say that the children of the public schools were less affected than the children under school age. A more interesting comparison is with the parochial schools, which were not at that time under medical inspection. The disease in these schools was widely prevalent, and a source of infection to the entire city.

Measles will always be the hardest epidemic condition to control, but with the present force maintained for school inspection, it is safe to say that the school children of the city will be less affected than children who are not of school age, and instead of the public schools being a source of spread of contagion they will be the safest places for the child. Children's parties, moving-picture houses, trolley cars, and Sunday schools are of far greater importance as a source of infection.

Diphtheria, Scarlet Fever.—In the last two years there has not been an epidemic of scarlet fever or diphtheria. From a comparison of the reports of the three years previous to 1915 a very prominent feature will be the pronounced increase in the number of cases of diphtheria in 1915-16. This is due to the fact that a culture was taken of every suspicious throat in that school year, with the result that nearly five times as many actual cases of diphtheria, or "carriers," were discovered as in any previous year of which there is a record.

There is no excuse for an epidemic of diphtheria or scarlet fever in the public schools of to-day. Though more virulent than measles, these two diseases are more easily controlled, and do not spread with the great rapidity after occurrence of the disease.

Control of Contagion.—When a disease of contagious nature appears in a school, and threatens to assume epidemic proportions, a nurse is stationed in that building, and remains her entire time in the building until the danger of epidemic is past. During this period the school doctor of the district also visits the school daily, and if necessary spends the entire time of his school hours in that building or

in making visits to the homes of absent children or cases excluded for observation.

The Exposed Room.—The room in which the outbreak first appears receives the careful attention of doctor and nurse. Each child is inspected, if diphtheria; or the non-immunes, if measles, whooping-cough, scarlet fever, etc.; and children who are regarded as suspicious are excluded from school for a period of observation in the home. If the disease develops, the case is quarantined; or, if the suspicious symptom disappears, the child returns to school.

Both doctor and nurse give a brief health lecture to the children, instructing them in certain preventive measures, such as gargling, castor oil, bathing, clean hands and fingernails, and staying away from quarantined homes and children.

The room, several times a day, is thoroughly aired and sunned; and at night, and in the morning, before school, undergoes a long period of open-air treatment. During the airing period, books opened loosely, and papers, are placed on desk tops so that the air can pass between the leaves. Desks and floors, and places where dust might collect, are scrubbed with soap and hot water. The room is then considered safe.

Home Visits.—When a child is absent three days from school the nurse visits the home to ascertain cause of absence, and, if illness, whether a physician is in attendance and whether the illness is of contagious nature. If there is doubt in the nurse's mind as to nature of illness, the school doctor is notified, who then visits the home.

In time of epidemic, or danger of epidemic, every absent child is visited the first day it does not appear in school. Nurse or doctor may make the visit, and examine the child to determine nature of illness.

Fumigation is regarded as obsolete, and of no practical value in school hygiene and sanitation as a preventive agent. It is never used except for psychological effect on nervous parents, principals or teachers, and others who require some concrete evidence of precautionary measures, such as strong odors, complicated and expensive apparatus, exclusion of children where they cannot be observed daily by the school authorities, steps quite in vogue in a day when mystics ward off evilspirits with weird and fanatic rites, penetrant vapors, fearful odors, and powerful extracts of toads, lizards, snakes, mice, and other remedial drafts which happened to be of prevailing popularity at that period. The theory, perhaps, was that any self-respecting germ would leave the vicinity rather than stand for such treatment.

Closing Schools.—There is no reason to-day for closing a school on account of contagion if a modern and efficient system of medical inspection is in operation. By actual experience we have been able to demonstrate that an epidemic can be confined to smaller limits and more easily controlled when children are in school, under continual observation, with the early exclusion and segregation of all suspicious cases. In fact, so great is the confidence of the parents in this system that it is a common occurrence for a nurse to receive a note from a parent requesting her to examine a child before entering the school room, as the child has developed suspi-

cious symptoms overnight. It is conceivable that a condition might arise, such as an especially virulent invasion of disease, when it might be necessary to close the schools. This is, however, a remote possibility.

The exclusion of children from moving-picture theaters, Sunday schools, trolley cars, and children's parties, should be considered before the closing of schools is considered. As soon as a school is closed because of contagion, children are thrown at liberty to mix freely at play, to go where they please, usually—home, theoretically, exposed to the elements, and removed from any trained or expert observation, thus rendering impotent any attempt to combat the disease.

A Simple and Accurate Record Necessary.—It has been found convenient to send to the parents blank forms to be filled, giving permission for the physical examination of the child. No simple or accurate way has heretofore existed by which we knew whether a child was immune from any of the childhood diseases, all of which would be of great assistance in preventing epidemics. Therefore, it is requested on the physical examination permits that the parent signify whether the child had ever had scarlet fever, measles, whooping cough, chicken pox, etc.

A record has thus been provided for us by which we know every child in the system who is immune or non-immune, so that when an outbreak occurs a nurse can enter the infected room with a brief record of those whom it will be necessary to observe closely. This clearly simplifies the work of epidemic prevention.

2. Vaccination.—Vaccination in New York State, as in other States, is a much discussed and disputed subject. The State law, till two years ago, required that every child be vaccinated before entering a public school. At that time, presumably as a "sop" to the anti-vaccinationists, the law was modified so that only public-school children of the first and second class cities had to be vaccinated, permitting the smaller cities and country districts, where health and sanitary regulations are more adapted to the propagation of disease, to be free of this "encroachment on personal liberty." While the law is perfectly clear in its intent, thousands of children in the State succeed in evading vaccination yearly in the cities where it is required. This is in part due to the opposition of parents, on one pretext or another, and partly to the ignoring of the law by the school authorities. Schenectady is at least one city in the State where the requirements of the law are fulfilled. True, it is not without opposition year after year, with stock protests ranging from "conscientious objection" to "religious principles." However, exemptions are only permitted where health or physical condition render vaccination inadvisable. A consideration of our methods and the results obtained should be sufficient to convince those opposed that vaccination can be performed with safety and without detriment to the health of the child; that is, sufficient to convince all except a certain type of "conscientious objector" who won't be convinced under any circumstances.

On the opening day of the new school year each child of the kindergarten and first grade is given a printed slip with a statement of the law requiring

vaccination, and a blank form to be filled in and returned immediately, if it is desired that the school physician perform the vaccination. With the exception of a comparatively small number these slips are returned the following day.

For the first two weeks of the school year the doctor's entire time is occupied in vaccinating. After the first two weeks, vaccination is performed once weekly for a month, after which it is only performed once monthly, completing the revaccinations, the stragglers, and those who have been excused because of poor health earlier in the year, but who have now been restored to good health.

Those who refuse to be vaccinated after the first two weeks of school are excluded, and notified that they cannot return to public schools till vaccinated. This generally results in some sort of response—either vaccination or court.

Method of Vaccination.—Where vaccination is performed on a large number of children under public auspices it is essential for the success of the undertaking that a uniform method be used, after it is learned by experience which is the best method. The technique used in the Schenectady schools is as follows:

The left arm is bared, and an area near the insertion of the deltoid is cleansed with alcohol and permitted to dry. An ordinary, medium-sized sewing needle, which has been sterilized in alcohol, is used for scarification, and is then discarded and a fresh needle used for the next child. A scarification of very small size is made, not much larger than the head of a match, and without drawing blood. A very small drop of vaccine is applied to this and allowed to dry, after which a sterile dressing is applied. The dressing is changed after four days, and after the first week each vaccination is observed daily and redressed.

Rosenau advises the Continental method, which is prescribed by law in several of the European countries. It is claimed for this method that with but two scratches, no scarification, complications are less frequent.

Our experience in Schenectady with the two methods is that with the technique described but one wound is produced, a smaller wound and scar results, the reactions are not as severe, and complications extremely rare, and due in every case to the interference or curiosity of child or parent.

Results.—In the two years during which vaccination has been insisted upon, 3,000 children have been vaccinated. Of this number 98 per cent. of the results have been successful. No serious complications have resulted, and but five severe reactions have been observed. It is safe to say that if an epidemic of smallpox should occur in Schenectady the public schools would be the least affected of any public or private institution in the city.

3. PHYSICAL EXAMINATION.—The State law requires that each public school child be examined once yearly. In no city in the State is it possible, with the existing medical inspection forces, to meet the letter of this law unless each child receives merely a perfunctory examination. In Schenectady it has been considered more advisable to be thorough than to establish a record for the large number of children examined annually. A greater effort has been made to secure the correction of the

defects found than to compile a vast column of accusatory defects as evidence of the fact that young America is a race of weaklings and the people becoming decadent.

Of 15,000 children in the public school in the 1916-17 term, 10,000 received physical examinations. A printed slip is sent home with each child, notifying the parents of the State law and stating that the examinations will be performed by the school physician if the parent desires it, and signs blank form to that effect. Commencing with the kindergarten, each grade is examined, the lower grades first. It is possible to reach about the seventh grade each year. Thus in the children in whom it is most necessary, the young children, defects are discovered and corrected at an early age, permitting normal physical and mental development.

In the physical examination the child is stripped to the waist, and receives a thorough chest and abdominal examination, and a more thorough examination if necessary. To prevent criticism and to protect the child from whatever embarrassment the normal child experiences, if any, the examination takes place behind a screen separating him from the other children. This feature is important, because each year some person of supersensitive morals is sure to discover the indecency and shocking immorality of the practice, and write letters to the city and State officials and the newspapers on the decadence of American purity and morals, as revealed in certain deplorable tendencies in our public schools. And we must protect our morals, by all means.

A Few Results.—One of the most encouraging results obtained is the improved condition of teeth, from kindergarten to high school. With our school dentists, our weekly lectures on oral hygiene, the toothbrush drills (more deplorable fads and follies in our drift from the little red schoolhouse of when Methuselah was a child), we are striking at the root of one of the important factors in the cause of ill health in children and adults. Normal physical and mental development is inconceivable in a child with badly infected and decaying teeth.

Tuberculosis—Building Backfires.—Another hopeful feature is a work which will have its greatest results in future years. *No public or private agency is situated more favorably than a modern public school medical inspection force for the combating of tuberculosis. No other agency has the strategic advantage of position for a great and prolonged drive against the great white plague.* When the great preventive fight is made in the schools the attack is directed at the great base of supply of the invader.

Two sure means of successfully attacking the disease are followed. All children, up to the seventh grade, receiving a careful examination every year, with the chest bared, offers the first means of discovering the disease in an early stage, or a predisposition to the disease—an attack on the flank.

The second method is an attack directly on the center, and cannot fail in eventually breaking through. Every intelligent school nurse knows the children and the families of her district. She is therefore enabled to become acquainted with the tubercular families of her district and incidentally the children of the families, who are naturally ex-

posed to the disease. In the Schenectady system these children are examined once monthly by the school doctor. If there is the slightest doubt as to their condition they are placed in an open-air school and kept there till they gain rugged health.

Thus there are two means of early discovery of the disease or the predisposition to the disease; by a thorough examination of all children yearly, and by a knowledge of the family history gained by the school nurse in her district work. With the open-air schools there is the means at hand of treating the condition as found.

On several occasions an attempt has been made to obtain a record of tuberculous families of the city. If such a record could be obtained, a map for each school district could be made showing the exact location of tuberculous cases, lung blocks, and other danger spots. The aid such a map would be to the school doctor and the nurse is obvious.

There is a State law, however, which keeps all such records under lock and key, and available only to the health officer and immediate assistants, after prescribed rites and secret ritual. The exact advantage of this health legislation is probably quite evident on deep study, and perhaps clever strategy in stamping out the scourge from an office chair. Superficially, however, it appears to have some disadvantages, and does not seem to be of marked assistance in reducing the tuberculosis rate in New York State.

Syphilis.—In the annual report of 1916-17 appear the records of 14 cases of syphilis. This is the first time that syphilis has been definitely established as an important factor in the health management of the Schenectady schools. As far as I know, it is the first instance of a public record of the existence of the disease in school children. While there is not at hand a voluminous collection of records to refer to, its apparent non-existence as a factor in the records available does not necessarily indicate that syphilis among school children is a discovery of the Schenectady Medical Inspection Staff. It does indicate, however, that *syphilis in the public schools is more prevalent than generally supposed by school or health authorities*, and that it is more prevalent in the Schenectady schools than indicated by the report, because our cases were obtained by a mere scratching of the surface, the diagnosis being plainly written on the children and substantiated by a positive Wassermann blood test.

Since the condition has been found greater effort should be made to find all congenital cases of syphilis in the public schools and secure the proper treatment. Might it not be the causative factor in many cases of chronic illness, mental retardation, feeble-mindedness, incorrigibility, juvenile delinquency, and tendency to criminality in children, where the cause is apparently obscure? That it might cause these conditions is not beyond the pale of possibility, because it was found to be the cause of fourteen such cases in the Schenectady schools! An intensive study of many troublesome cases in the schools frequently discloses many surprising conditions for which there is a remedy!

Other prominent features of the reports are the number of curvatures of the spine in an early stage of development, not found in less thorough examina-

tions; the really large number of conditions found producing ill health and mental retardation in children; and other features found in any well-balanced system of medical inspection.

4. SPECIAL FEATURES.—(A) The Open-Air Child. (B) The Mentally Atypical Child. (a) The Backward Child. (b) The Feeble-minded Child.

A. *The Open-Air Child.*—Four open-air classes are maintained, each being located conveniently for different sections of the city. The open-air classrooms have been constructed especially for the purpose, and are situated on the roof of the school building, with a roof playground attached. At present each open-air department is equipped and operated for about thirty children, with a capacity for fifty children, in anticipation of the future growth of the city during the next few years at least.

The child, on admission is provided with a clean woolen suit and hood, gloves, felt boots, and a woolen sleeping bag, and thus warmly clad is fortified against the Arctic temperature which frequently prevails in Schenectady.

A thorough physical examination is performed by the school doctor, and includes a hæmoglobin test, height, weight, and mental examination. The school nurse also visits the home of the child and advises on the proper food, hygienic conditions, and other corrective measures. A weekly record of weight is made, a frequent hemoglobin test taken, and temperature recorded daily in cases where necessary. There is no definite period for attendance in an open-air class, the child continuing till established to a rugged state of health, whether several months or several years are required. When it is considered safe to return a child to the regular grades this is done, but the child remains under observation.

A *Feature of Prime Importance.*—One substantial meal is provided daily, and consists of at least 900 calories food value, which is about 200 calories more than necessary for the average child. No attempt is made to approximate a hospital standard of diet, as the type of child in the open-air class does not require an invalid or semi-invalid menu. Suffering very often from malnutrition, due to lack of food or improper feeding, a *regular* meal of wholesome quality is required. Temptingly prepared by experts whose chief mission in life seems to be the conception of delicious nutritional gems, dinner is served in cheerful surroundings to eager youngsters in an advanced stage of starvation, having had nothing to eat since breakfast. If one is of the opinion that the open-air-class child would thrive better on a pampered diet, a visit at the very popular lunch hour should allay all fears. Of the several hundred children who have attended these classes no record exists of any who have refused the food.

A carefully balanced diet has been prepared by the Supervisor of Domestic Arts, who also directs the preparation of the food. This eliminates the possibility of waste, and has the additional advantage of uniformity of feeding, enabling the purchase of food supplies in bulk at greatly reduced cost. Despite the present high prices of food we have been able to feed the youngsters at only an increase of 1½ cents per meal per child without cut-

ting down either the quality or quantity of food. The cost at present is about nine cents per meal.

After lunch each child brushes the teeth, and then, wrapped comfortably in a warm sleeping bag, lies in the open air on a cot till the afternoon session commences. If sleeping at the opening of the session, the child is not disturbed, but is allowed to sleep, and returns to the class on awaking.

A New Phase.—It is important to note here that in cases where there is a persistent temperature, but no other symptoms of an active tuberculosis, attendance at the morning session is permitted; but following lunch it is required that the child sleep in the open for several hours. After several weeks the temperature subsides and the patient is permitted to return to the afternoon session. This is distinctly better than excluding the child from even the open-air school, to roam perhaps at will, or to be confined in unsuitable quarters in the home. Thus the open-air schools have entered upon a new phase of usefulness, subject, of course, to the objection of the chronic objector, "that the public school is not a hospital."

The open-air schools have introduced a very human feature into the public schools of to-day. The weakling, the child predisposed to tuberculosis, the child of malnutrition, whether underfed or improperly fed, is now able to receive an education and at the same time benefit in health. Human material, formerly waste, is reclaimed. A useful citizen is saved to the community—a most practical consideration.

B. The Mentally Atypical Child.—(a) *The Backward Child.*—Always in a school is the problem of the backward child; the over-age child, retarded in grade, who retards the normal progress of the other children; who is a source of embarrassment to parent, teacher, and pupil, and who suffers humiliation constantly because of mental inferiority to younger children. Of recent years a certain percentage of these cases have been found to be due to remedial causes, such as pronounced anemia, adenoids, defective vision, defective teeth, deafness, thyroid deficiency, and other very evident physical imperfections.

Those actively engaged in health work among school children are constantly encountering cases of mental retardation due to some physical defect or to an economic or social factor. In order to approach the matter from an angle which would permit of accurate deductions, in the spring of 1917 a study was made of (1) the health, (2) the physical condition, (3) habits, (4) home conditions, of 100 backward children, every case referred by the school principals. Without entering into a detailed discussion of the result of this most interesting study (a report of which is being prepared), it can be stated that in 95 per cent. of the cases some gross condition could be assigned as a definite cause of the backwardness. To establish a more efficient working knowledge by which to proceed in such cases, a thorough study should be made of every case of mental retardation, an accurate system of records should be maintained, the apparent cause corrected, and an observation of the result be carefully noted. Thus will the solution of this problem be approached from a scientific basis.

(b) *The Feeble-minded Child.*—A problem of so

great magnitude as the care of the feeble-minded, and one so vitally related to public welfare, is essentially a State responsibility. Few municipalities are in a position to equip and maintain an institution for the feeble-minded. Even if cities or counties were able to assume such a burden, it would not only be a waste of public funds but an ineffectual method of procedure. If so serious a social evil, linked inseparably with pauperism, crime and prostitution, is to be attacked with any hope of solution, nothing but a scientific co-ordinate effort offers chance of success. Obviously it is out of the question to expect forty or fifty different agencies, cities or counties working separately, to secure a successful result. Equally obvious is the fact that the State is the only agency capable of concentrating forces and scientifically organizing and directing the work. The State, however, is not prepared to accept full responsibility at present, having neither adequate institutional facilities nor a definite program for combating the condition; eventually, no doubt both deficiencies will be remedied. Until then, cities will have to depend on their own initiative, and accept what limited aid the State is prepared to extend.

The Role of the Public School.—In any policy that a city adopts toward providing for its feeble-minded population, the public schools are bound to assume a very prominent rôle. This will undoubtedly be true of any plan which the State ultimately develops. It is practical, then, that schools proceed along conservative lines to organize a rational system for caring for the feeble-minded child, always bearing in mind that such a child because of its amentia *is not destined to become a useful member of society.*

The problem, therefore, is not one of reclamation. It is not a question of conservation of human material. Rather, it is a question of elimination from normal life of burdensome material. Manifestly, any system which contemplates the preparation of the feeble-minded child for normal intercourse with society, for competition of normal life and its constantly increasing demands for existence, is based on an impractical premise. A system, however, which is established on the principle that the public school is simply a "clearing house," an intermediate station between the home and the institution, is founded on a practical basis. The work conducted with this idea, with the chief feature an *early recognition* and *segregation* of this type of child, is fulfilling the highest possible function, performing the most humane and greatest service to the child and society; but therein lies a difficulty. On whom is the early recognition to depend? Who in the school system is qualified to definitely state that a child is feeble-minded? It is a delicate procedure to direct that a child be transferred from a grade of normal children to a special class for feeble-minded children. It is stamping a child as mentally incompetent, socially unfit, as an undesirable unit of a community, a potential menace to the safety and welfare of the public; and the decision is often by a very slim margin. Data must be complete, the case must be positive! Who is to make the diagnosis?

A Type of Diagnostician.—A few years ago it was recognized that the feeble-minded individual is a serious economical and social factor of public

importance. Feeble-mindedness seeming, as it did, to account so well for a high percentage of pauperism, prostitution and crime, was immediately pounced upon by some enthusiasts as a solution for the backward child, the dullard, the laggard in the public schools. So-called experts sprung up overnight prepared to eliminate this very perplexing condition by the proper classification and segregation of all such pupils into special classes. Their chief qualifications for the work consisted of a brief course in an institution for the feeble-minded, and an acquaintance with one or more of the mental tests, which could not be termed exactly intimate. Obviously they were considering a very important matter, with not only an imperfect conception, if with any understanding at all, of the difference between a backward child and a feeble-minded child, but with inaccurate methods.

They knew that in almost every grade, one or more children were over normal age and still unable to make progress. They also found that on a mental examination, many of this type would test below normal for their age. They did not know, however, that certain physical conditions could impede the mental progress of a mentally normal child. They did not know, or did not recognize, that a high-grade Ament may, on a mental test, appear to far better advantage than some mentally normal children, or may even attain a higher scholastic standing. Other details, such as personal and family history, social and economical conditions, or a thorough physical examination, were apparently of no importance. But with a long-standing and troublesome educational flaw to be remedied, and with a comparatively simple method of connection at hand, so to speak, they proceeded to eradicate this most undesirable feature, and chaos followed. Even in this day of enlightenment, ideas, methods and results have made little progress in many quarters.

It is a matter of extreme importance to the public and justice to the child that a diagnosis of amentia be made only after a careful and scientific development of every phase of the case. Before a positive decision is possible, a personal and family history have to be obtained, the information being derived from every available source, from the home, relatives, the school and court; the social and economic factors require investigation; a complete physical examination, including serological, is imperative and, of course, a mental examination. When all materials are assembled and compiled into a record, the complete history is balanced and judged by a capable and experienced specialist. Obviously a matter of so considerable importance is not for inexpert or inexperienced hands. Notwithstanding, far too often are cases disposed of by immature judgment. A working knowledge of the different systems of mental tests is considered by many to be sufficient for diagnosis; but the fact that a child tests several years below normal on a certain scale at the time of examination is not a criterion of amentia. Nor does retardation in school, incorrigibility, juvenile delinquency and a test below normal on a mental scale constitute feeble-mindedness. True, these features are prominent concomitants of feeble-mindedness, and are important points in obtaining a history, but like conditions exist in children not mentally deficient.

Since the feeble-minded child is a factor of importance in public schools, important because it is necessary to separate such a child from normal children, and present in numbers estimated as high as 2 per cent by some authorities, there is no alternative but to meet the condition, as any other problem, and in doing so it must be borne in mind: That this type of child will never be a desirable member of society. That the public school can best serve as a "clearing house" for the institution. That the early recognition and segregation comes only within the sphere of the specialist.

Failure to recognize a high-grade feeble-minded child of the border-line type, because of inefficiency of the examiner, is a great misfortune. On the other hand, if a mentally normal child is branded as feeble-minded by the inexpert or inexperienced, with only a superficial knowledge of the condition, it is a disaster.

The Schenectady Policy.—The policy which the Schenectady Public School system has adapted toward the feeble-minded child in the schools is based generally on the above principles. Life in an institution is considered to be the most desirable for the mental defective. Recognizing the futility of offering a suitable training outside of an institution, efforts are directed more toward a preparatory training for the institution.

Four classes for mentally defective children are maintained, each class being in charge of teachers who have specialized in that work. Fifteen pupils are assigned to each class. Before admission to the class, a child undergoes an examination by a specialist. The child is brought to the "clearing house" by the mother, accompanied by a school nurse. A personal and family history is obtained from the mother and several subsequent visits may be necessary. The school nurse has ascertained the social and economic conditions of the home, school and court records also accompany the case; and the child is examined both mentally and physically. Records are maintained of every case examined and are valuable for references and statistical purposes. When it has been definitely established that the child is a true case of amentia, a transfer is made to a special class and the relatives advised of the importance of having such a child committed to an institution. It is of interest to note that several very urgent cases have been admitted to State institutions recently, very shortly after application had been made. This is an encouraging sign of improved State facilities.

The great possibilities of school medical inspection are probably not fully realized. Though wonders have been accomplished the work is still in the pioneer stages; even so, it has almost reached the period where it convinces the skeptic that school health work is not a fad. Certainly no public health work has a greater motive than the production of strong, healthy bodies and minds. In this day, the type of man and woman of to-morrow is a most urgent consideration.

With the State physical training laws, and with oral hygiene drills and weekly health lectures, teaching simple rules of health and hygiene from kindergarten to the higher grades, who knows but that in the future, health lectures will become a part of the curriculum.

Even now a new field seems to be unfolding for the school health worker. Though it is too soon to make more than a preliminary report of two years' observation, a certain type of child who was formerly sent to reform schools has been kept in the public schools, without interfering with the normal progress or the morals of the school, and with marked improvement in the child. One notable case is that of a fourteen-year-old boy, who had not spent more than three months away from a reformatory since he was nine years of age, but under treatment has attended school for nearly six months without being tardy, with only one day's absence, and according to the last report, in the words of his teacher, "has been all any teacher could ask for," and, "he is interested in his studies and anxious to get his lessons," and, "is an unusually bright boy."

Truly, the possibilities of school health work are not fully realized. Public school medical inspection has arrived, and it is here to stay.

515 STATE STREET.

WASTE CAUSED BY PREVENTABLE DISEASE OF INTESTINAL ORIGIN.*

By VICTOR G. HEISER, M.D.,

NEW YORK.

A VERY pleasant privilege has been accorded me to say a few words before the Academy, and I shall endeavor to show my appreciation by being as brief as possible. It is refreshing to come from the fields of slaughter to find here an association so hopefully at work for conserving human life and for promoting the well-being of mankind. The other speakers have already dealt with various phases of health as factors in national efficiency. I wonder whether sufficient emphasis has been placed upon the enormous amount of pain, misery, unhappiness, sickness, and death that is caused by preventable intestinal disease. It is well within the bounds of conservatism to state that over 127,000 persons in the United States die annually from causes acting in and through the intestines. In other words, from swallowing something unclean which might easily be avoided. To this must be added other hundreds of thousands who are made ill or are incapacitated from the same causes.

The economic losses are estimated at enormous totals. For instance, Dr. Allen S. Smith of the University of Pennsylvania states that hookworm disease in the South causes between \$250,000,000 and \$500,000,000 damage per annum. Stiles states that the very conservative estimate of 50 cents loss per week for each person suffering from hookworm disease gives a total of \$50,000,000 per annum. Ellis estimates that typhoid fever costs the United States \$350,000,000 annually, and as an instance he cites the fact that before the city of Pittsburgh had a safe water supply this disease in one year was estimated to have cost the city \$3,142,000. Ellis also estimates that in the State of South Carolina alone the hookworm losses are \$30,000,000 per annum. The State Board of Health of Louisiana estimates an annual loss of \$3,000,000 from hookworm disease in that state. Gunn estimates that the loss from hookworm disease in one mine in

California which employs 300 men is \$20,000 per year. The construction of the St. Gotthard tunnel through the Alps was almost completely stopped by disease among the laborers, until it was discovered that the illness was caused by the lack of proper disposal of human excrement. Again, Stiles estimates that 30 per cent of the education in the Southern States is wasted owing to the backward mentality caused by hookworm infection. Clayton Lane has just published a statement showing that the entire war debt of India could be paid by wages which are lost by Indian hookworm victims, and yet we know that wages in India are a mere pittance compared to American standards. So far we have mentioned only typhoid and hookworm infection. To these must be added the losses caused by diarrhea, dysentery, cholera, and a host of other diseases.

Then there is also an enormous indirect loss. Hazen, for instance, showed that each death avoided from typhoid fever prevented two or three other deaths from other diseases. This theory has frequently received confirmation. For example, in Manila, in periods during which water from an uninhabited watershed was used, there were 3,000 fewer deaths per annum than when the water supply was taken from an inhabited watershed. The deaths from practically all causes declined by changing the source of the drinking water; there was a reduction in the number of deaths from pneumonia, from tuberculosis, nephritis, and from other affections not ordinarily associated with intestinal disease.

The Remedy.—It may be asked what can be done to prevent this enormous waste. The answer is simple. It is only necessary to provide for the safe disposal of the excrement of the entire population. In most of our cities the problem has been largely solved through the water carriage of sewage. Yet I am told that even here in Philadelphia there are thousands of open privies which may be a menace to health through the agency of flies and other contact contaminating human food and drink. The great bulk of the trouble, however, is in rural communities. It has been the popular belief that the health of those who live in the country is much better than the health of those who live in the city. This could probably be made so by the observance of ordinary hygienic precautions. But let us look at the actual conditions. In a survey of more than 200,000 school children in New York City, compared with 200,000 school children in rural Pennsylvania, it was shown that disease was at least four times as prevalent in rural Pennsylvania. Death rates in the country are higher. A large percentage of the ill health in the country districts is due to primitive latrine conditions. There are many areas in this country where no form of latrine exists. By careful surveys it has been demonstrated in many sections of the United States that only 50 per cent. of the houses have latrines of any kind. The remedy is very simple, and easy of application. No great engineering works are necessary, and the method of prevention can be demonstrated to the most ignorant. There is no community in this country which does not have sufficient resources to carry out the safe disposal of body discharges.

*Read before the American Academy of Political and Social Science, Philadelphia, Pa., April 26, 1918.

The meager evidence here presented shows that

the loss caused by only a few of the intestinal diseases will total to more than a billion dollars per year. Efficiency is the watchword of the day. The struggle for existence after the war will probably be keener than ever. Shall we enter the contest with this handicap, or shall we strike it from us?

REPORT ON WAR TIME NURSING PROBLEMS.

BY

THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.*

Number of Nurses in the United States. According to the information gathered by the national nursing organizations, there are between eighty and one hundred thousand registered nurses in the United States. The last estimate, made by Miss Mary C. Wheeler for the American Nurses Association, places the number of registered living nurses at 98,006 exclusive of the states of Nevada, New Mexico, and Arizona which have no registration laws. In this number, of course is included the nurses who have retired from work because of age, marriage, or for other reasons. This number also includes the probable six to ten thousand nurses in public health work.

Number of Nurses Needed for War Duty.—There is no definite basis for estimating the total number of nurses needed for war duty. The nearest approximation to an estimate, which we have been able to get, is as follows: The number of sick and wounded is estimated at ten per cent of the armed forces; therefore, for an army and navy of two million men, two hundred thousand would require nursing attendance. It is estimated that two hundred thousand sick and wounded in the army and navy will require about 25,000 nurses.

Up to the present time a little over 9,000 nurses have enlisted, and a call has been issued for the enlistment of one thousand a month henceforth.

The recruiting of nurses is done chiefly through the agency of the Red Cross, although a small number of nurses have been obtained by the Army and Navy directly. Thus far only full-trained, graduate nurses have been recruited for Army and Navy work.

Nursing Situation.—In spite of the fact that only 9,000 have thus far entered the military establishment, a shortage of nurses has already become apparent in hospitals, particularly the smaller ones which have no training schools, and in private practice. The American Nurses Association has looked into the matter of the shortage and reports that until several months ago most of the registries had available nurses, but since then all of the nurses are busy all the time. This shortage may be alleviated

*The membership of the Public Health Committee is as follows: Charles Loomis Dana, M.D., Chairman; James Alexander Miller, M.D., secretary; John S. Billings, M.D., Nathan E. Brill, M.D., Robert J. Carlisle, M.D., Floyd M. Crandall, M.D., Lewis Fox Frissell, M.D., Arpad G. Gerster, M.D., S. S. Goldwater, M.D., John A. Hartwell, M.D., Thomas W. Hastings, M.D., L. Emmett Holt, M.D., Abraham Jacobi, M.D., Howard Lilienthal, M.D., Walter L. Niles, M.D., Bernard Sachs, M.D., Thomas W. Salmon, M.D., Frederic E. Sondern, M.D., J. Bentley Squier, M.D., W. Gilman Thompson, M.D., Frederick Tilney, M.D., Philip Van Ingen, M.D., Karl M. Vogel, M.D., George B. Wallace, M.D., Herbert B. Wilcox, M.D., E. H. Lewinski-Corwin, Ph.D., executive secretary.

somewhat by an appeal to those who employ private nurses to conserve the nursing service by employing them only when it is absolutely necessary, and then to employ the minimum number needed.

In this country we have approximately 1,500 training schools with a registration of 40,000 students, turning out annually about 11,000 graduates. The period of training in most of the schools is three years. The entrance requirements call for a full high school education in only 5 states; in 28 states only one year of high school is required; and in 13 states the grammar school education is sufficient. The remaining several states do not specify any preliminary educational requirements.

Many of the training schools have less than their full quota of pupils, and can accommodate more. A few training schools, already supplied with their full normal quota of pupils, are renting additional buildings in which to accommodate surplus applicants. The efforts of the Nurses Association are directed toward bringing to the training schools as large a number of students as is possible, in order to train a large number of nurses, and to release graduates whose places in the hospitals, to a limited extent, can be taken by pupil nurses.

Over 400 young college women have been enlisted for nursing work under the auspices of Vassar College. They are to get several months of theoretical training at the College, and in the autumn will be distributed among the various hospitals of the country for two years of practical training. Those in charge of this work seem to think that these young women represent a very desirable element in the nursing profession and can be relied upon to finish the course.

The suggestion of drafting girls for nurse duty is evidently not to be considered seriously.

The proposal to reduce the term of training school instruction from three years to two years is also not to be recommended at the present time in view of the fact that it will not materially improve the situation as far as the immediate supply is concerned, and would simply act as an entering wedge for lowering the standards of nursing education. It is not desirable to lower the educational requirements for entrance into the training schools.

The establishing of schools for nurses under army auspices has been widely discussed and according to report is receiving official consideration. It is a question to what extent such schools could attract women who would not otherwise consider entering the nursing profession. The mere diversion of a part of the normal supply of pupils from civil to military hospitals would not solve the problem.

In addition to the registered graduate nurses, we have in this country about 115,000 partially trained nurses who, for one reason or another, failed to complete their training school courses, but who have had experience in private practice and who oftentimes make good and reliable bedside attendants.

The Red Cross has also instituted short courses in connection with base hospitals for the training of voluntary aids, as they are called. Something like two thousand young women have taken this training (451 in New York City), both theoretical and practical, during the past year, but they have not been sent abroad; all of them have been kept in

this country, some doing canteen work, others taking up public health and similar work. Many of them are still idle. Several thousand, in addition, have taken the preliminary lecture course and are awaiting an opportunity to complete their training in hospitals. The only apparent obstacle to such training in New York City appears to be the official opposition of the State Education Department, whose disapproval, recorded nearly a year ago and as far as we are aware not since reconsidered, was based upon the belief that the needs of the State and of the nation during the war could be met by the enrollment of pupil nurses in the ordinary way.

It is our understanding that the Surgeon General's office does not wish to utilize the services of aids until all the sources of regular nursing supply have been exhausted. The civil hospitals, generally, are willing to train aids in large numbers, and to use them in case of need. Twelve hospitals in New York City are to-day utilizing the services of a limited number of aids and are on record as finding the plan wholly practicable. There are a great many women of good social standing in this country who, prompted by patriotic motives, earnestly desire to enter this field.

The training of non-professional, voluntary aids, with proper limitation, selection, and control, would meet pressing needs quickly and with the least disturbance of professional nursing standards during or after the war. It is of course understood that the principal efforts of those interested should be directed toward increasing the supply of regular pupil nurses, and that under no circumstances should young women be encouraged to enlist as aids who can be persuaded to enter the ranks of pupil nurses.

Recommendations.—1. Training school facilities in connection with each hospital should be enlarged to the fullest capacity.

2. Young women desiring to be of service in the war should be encouraged to enter regular training schools rather than to take a brief course as nursing aids.

3. Professional nursing standards should not be lowered.

4. The establishment of Army training schools for nurses should not be undertaken on a large scale, on account of the probable unfavorable reaction on the civil hospitals, but one or two Army training schools might be established experimentally.

5. A corps of partially trained women might advantageously be organized to serve as attendants in Army hospitals.

6. Accredited civil hospitals in cooperation with the American Red Cross should undertake the training of nurses' aids for gratuitous service only.

Familial Mammary Cancer.—Leschcziner reports the instance of a mother and three daughters all of whom developed cancer of the breast, dying therefrom. As has been noted before in familial cancer the disease appeared very early in life, the ages being 21, 14, 19, 22. The course, however, was slow with late metastases. Three of the cancers were examples of colloid.—*Medizinische Klinik.*

Medicolegal Notes.

Certification and Registration.—The Texas Court of Civil Appeals holds that, under the State statute, Pen. Code 1916, art. 750, making it unlawful to practise medicine without registering authority with the district clerk in the county of residence and providing that absence of such record is prima facie evidence of want of such certificate, the state must prove such absence from the record in an action for practising medicine in violation of the statute. The defendant's claim that the evidence showed he was engaged as a masseur and exempted under article 754 of the Code from the provision of article 750 requiring registration for the practice of medicine was held not sustained as a matter of law; his occupation being a question of fact for the jury.—*Denton v. State (Tex.)*, 201 S.W. 183.

Limitation of Time for Commencing Actions for Malpractice.—The California Court holds that an amended complaint, alleging that the plaintiff entered into a contract with the defendant, a corporation operating a hospital and carrying on therein the general business of furnishing medicine and medical and surgical treatment, ambulance and hospital care to the sick and injured, by which the defendant agreed to furnish the plaintiff medical and surgical treatment when the same should be necessary; that the plaintiff suffered a fracture of certain bones of her leg, rendering surgical treatment necessary; that the defendant undertook through its chief surgeon to render and furnish such treatment; that the surgeon was incompetent, and failed and neglected to use proper care, diligence, and skill in reducing the fracture; and that by reason thereof the plaintiff's leg was shortened and its use impaired—shows that the gist of the plaintiff's action, notwithstanding the statements as to the contracts, was the negligence of the defendant's chief surgeon and not breach of contract. The California statute requiring actions for injury to or death of one caused by the wrongful act or neglect of another to be begun within a year, therefore applied to the action, which must be commenced within one year after the negligent act.

In the recent case of *Marty v. Somers*, 169 Pac. 411, in which a rehearing has been denied by the California Supreme Court, this precise question arose upon an identical state of facts. There the contract of employment was directly with the physician, who was alleged to have negligently performed the operation which caused the plaintiff's injury, and the court there held that the statute above mentioned operated as a bar to the action. The authorities from other jurisdictions dealing with cases of alleged malpractice on the part of physicians are not uniform in their rulings as to whether the action is one arising upon contract or tort. But the case of *Lotten v. O'Brien*, 146 Wis. 213, 131 N.W. 362, bears instructively on the present case. Its facts were similar. It appeared that the employment of the physician continued for some time after the date of the negligent setting of the plaintiff's broken arm. The court held that the action sounded in tort, and that the cause of action accrued when the negligent acts were committed, without reference to the time of the physician's discharge. As the action in the present instance was not commenced within a year after the negligent act, judgment for the defendant was affirmed.—*Hardy v. Liberty Hospital Corp.*, California Supreme Court, 171 Pac. 98.

Exemption of Hospitals from Taxation.—The South Dakota Supreme Court holds that a hospital which received sick persons, other than those afflicted with contagious diseases, extending treatment free to paupers, charging for its services to others to the extent of what they were able to pay, devoting all its property to the purpose of treating its patients, who had been approximately 95 per cent. pay patients and 5 per cent. charity patients, using any surplus funds to keep up and improve its property and pay interest on bonded indebtedness, and maintaining a nurses' training school, was a "corporation or society organized and conducted exclusively for charitable purposes," a public charity, whose property was exempt from taxation under the South Dakota statute.—*Lutheran Hospital Assn. of South Dakota v. Baker*, South Dakota Supreme Court, 167 N.W. 148.

Military Medicine.

SOME PROBLEMS OF NUTRITION IN THE ARMY.*

FOOD has been defined as a well-tasting mixture of materials, which, when taken into the stomach, is capable of maintaining the body in any desired state. The choice of these mixtures in the form of menus, their preparation, their digestion and fate in the body, constitute the science of nutrition. If we had definite knowledge of every food substance and the transformation it undergoes in the body, just what purpose it fulfills and how it fulfills this purpose and what becomes of it afterwards we should have a *completed* science of nutrition. A person is satisfactorily nourished when he is maintained in a physical and mental status.

In our Army the first requisite was to create a body of well muscled men and this is being rapidly achieved. In the muscle-up period a plentiful amount of muscle-forming materials, the best of which is beef, is required. The first legislation fixing the components of the Army ration is dated November 4, 1775, when the Continental Congress fixed one pound of beef and one pound of bread as the allowance for each man per day, "three pints of beans or peas at a price not to exceed \$1.00 per bushel, one pint of milk, half a pound of rice or one pound of Indian meal per week, one quart of spruce beer or cider for each man or nine gallons of molasses for each company of men per week." The ration also included candles and soap. The ration fixed July 16, 1798, is in some respects the same as we have to-day. In 1818 Calhoun who was Secretary of War recommended that the liquor components of the ration be discontinued. This was concurred in by Surgeon General Lovell. Congress, however, failed to act, and the liquor continued as a component of the ration until 1838. In 1817 Andrew Jackson who was Commander of the Army became so impatient with the contractor system that he organized a commissary department for his own army entirely without authority from Congress. This resulted in legislation dated April 11, 1818, which laid the foundation of our modern Subsistence Department. In 1832 coffee was for the first time made a part of the ration. The ration which prevailed throughout the Civil War, fixed by legislation dated August 30, 1861, was as follows:

Beef 20 ounces.
Bread or flour 22 ounces.
Potatoes 16 ounces three times a week.
Beans, rice or hominy "in proportion with above."
Then for each company of men or 100 rations:
10 lbs. coffee.
15 lbs. sugar.
4 qts. vinegar.
4 lbs. soap.
1½ lbs. candles.

Besides the "garrison ration," fixed by legislation dated January 11, 1911, the American Army has the reserve ration, the travel ration, and an

*Abstract of a paper read by Major John R. Murlin, Sanitary Corps, National Army, Chief of the Division of Food and Nutrition of the Surgeon-General's Office, at the April meeting of the College of Physicians of Philadelphia.

emergency ration. The last named has been well defined "a substitute for nothing." The Division of Food and Nutrition in its effort to find a satisfactory emergency ration has not been entirely successful but believes that the most satisfactory form of concentrated ration is hard bread supplemented by potted beef or ham, dried beef or sardines, and when there is opportunity for the use of a portable cooker, three ounces of sliced bacon should be added. The ration forming the basis of feeding in training camps does not prescribe what the men shall eat. It is merely used as the basis of money allowance for the ration. A long list of substitutive articles is carried by the Quartermaster Department but the soldiers must not spend more than the amount of money represented by the cost of the garrison ration, with certain definite percentages of substitutions, at the time and place where they are stationed. If the men do not like what the Quartermaster has in store they are at liberty to take money from the Quartermaster in lieu of rations and buy materials outside. This is at the discretion of the commanding general. On the whole it must be said that the mess system in vogue in the American Army works well. The work of the Division of Food and Nutrition is not to supply food for the Army. Its duties are largely of an advisory or inspectorial nature. It is authorized to inspect all the food of a camp with especial reference to its nutritive value; to seek to improve the mess conditions; to determine the actual consumption of food and amount of waste and to report these facts to the Division Commander. The Division now contains 65 officers and some 50 enlisted men. A Nutritional Survey party, consisting of four officers and several enlisted men spends from two to four weeks in a camp studying food conditions and making recommendations and then returns to observe improvements. One contingent has gone abroad to report to General Pershing for similar service in France. Already the Food Division has been able to improve food conditions and has already gathered a considerable mass of information regarding the actual consumption of food and the amount of waste. Recent reports from Camp Funston and Camp Sevier show that waste has been reduced to a practically negligible point. Company commanders at their discretion can compel a man to eat at the next meal anything he has left on his plate. We find that the most economical way of serving men in large numbers is by the squad system in which the squad leader shall have authority over the serving of his men. Our work has given the first instance in warfare in which the actual amount of food consumed is estimated directly in the camp and field. This is made possible by our system of feeding men by companies. Meat is the most economical repair material for muscle and other active tissues. The British Army allows 1 lb. of meat per man per day; the French Army, ¾ lb.; the Italian, ½ lb. Our allowance is 1¼ lb., but the actual consumption in the camps in this country does not exceed ¾ lb. The question may fairly be asked whether the Government would not be well advised to reduce the quota of meat and replace the amount thus saved with sweets, provided as a part of the ration. The dehydration of vegetables is a question of great in-

terest to the Army and the Quartermaster Department has placed orders for dehydrated potatoes, onions, and carrots for the use of General Pershing's Army. By simply soaking in water and boiling in the same water these vegetables are brought back to the condition of fresh vegetables and often cannot be distinguished from them. The saving of time in the company kitchen is also a highly important element. The Division of Food and Nutrition has already found a method of making meat powder by dehydration of these food products. At the request of the American Red Cross the Food Division prepared an American prisoners' ration which could be shipped to the Red Cross Headquarters at Bern, Switzerland, and packed in parcels not to exceed 11 lbs. This was sent three times every two weeks. The list was somewhat as follows: Rice, sugar, dried beef, pork, and beans; peanut butter, soda crackers, evaporated milk, milk chocolate, desiccated strawberry, jam, nutmargarine and dried figs. At the request of the Red Cross was also prepared a ration to be known as the invalid ration. The following ration has been approved by the President and adopted: Unpolished rice, yellow cornmeal, sugar, potted chicken, Julienne, or compressed soup tablets, dried milk powder or Horlick's malted milk, beef extract, minute tapioca or other form of prepared pudding, crackers, tea, milk chocolate, marmalade, fresh fruit or fruit juice. These articles, however, are regarded as only supplementay to those of the regular ration.

Latent Syphilis and the Traumatisms of War.—Vignolo-Lututi writes at length on this subject in *Il Policlinico* for February 17. He calls attention to the tendency of tertiarism to attack the point of least resistance, as scrofulous glands, alcoholic liver, mouth and throat of smokers. Such area of lessened resistance are also furnished by traumatism of all kinds, including slight irritation. As an illustrative case he mentions an officer of 28 years, the bearer of many wounds. One of these, on the right shoulder, which had presented nothing peculiar while healing, began all at once to assume special characteristics, while certain manifestations appeared in the immediate vicinity and began to ulcerate. The wound and the superadded lesions were seen to be gummatous. This kind of behavior is well described by Fournier in connection with "bleeding" wounds. It was found that the officer had been infected six years earlier and had received very irregular treatment for three years. His general resistance had doubtless been lowered by years of military life and just why only one of a number of wounds had attracted the disease does not admit of explanation. The Wassermann of this patient was found to be strongly positive and the specific lesion disappeared rapidly under calomel hypodermics. The author saw a similar case before the war, in a woman of 40 who had received numerous contusions as the result of a fall. One bruise in the right leg was transformed into a vast gummatous ulcer. She had been infected twenty-two years before, at the time of marriage. The Wassermann was positive. The patient was inoculated on the arm with matter from a chancre and a gumma developed, an experience first described by Fouger and Landsteiner.

Queyrat and Pinard once described a case in a boy of seven, who had been kicked by a horse and had developed *in situ* an ulcerated tertiary lesion. They inoculated the boy with matter from a chancre and in 21 days a gumma appeared in the inoculated point. The appearance of provoked lesions in latent syphilis has been explained by a theory of lowest local immunity. An attempt has been made to distinguish between monosyphilide and polysyphilide periods of latency. The former would naturally occur at a late period of the disease. However, there is also a late polysyphilide period and this again may be subdivided, according as the lesions develop at different points of local irritation or appear spontaneously. In the latter case the general immunity is weakened. In regard to lowered local immunity it is known that spirochetes may persist in certain localities without any evidence of a tissue reaction in which state they could be regarded as saprophytes. Irritation of such localities could arouse them to virulence. From another angle the organisms may exist passive in the deeper tissues—bone marrow, for example—and then for some reason enter the circulation and be deposited in an active state in the skin or elsewhere. Under such circumstances multiple lesions could arise like ordinary metastases. In the author's cases he is forced to conclude that spirochetes must have pre-existed in the wounded tissues in which developed the gummous manifestations.

Campaign for Organization of Volunteer Medical Service.—The General Medical Board of the Council on National Defense has started a campaign to organize all physicians ineligible for camp or field duty into a Voluntary Medical Service Corps. The members of this corps will be classified according to their ability to serve and will render aid to existing governmental agencies upon request of the Army, Navy, or Public Health Service, American Red Cross, or Council of National Defense. It is hoped that every physician who is unable to enroll in the Medical Reserve Corps will join the Volunteer Medical Service Corps. Applicants for service in the Medical Reserve Corps who have been rejected because of physical defects that may be overcome are urged to have such defects remedied and therefore become eligible. The general management of the Volunteer Medical Service Corps is vested in a Central Governing Board, which is a committee of the General Medical Board of the Council of National Defense. The procedure for joining is simple. The applicant returns his filled blank to the Central Governing Board in Washington, and it is then referred to the proper State Executive Committee for its recommendation as to the qualifications of the applicant, and as to the kind of work for which he seems most fitted.

Red Cross Makes Record.—During the month of April, the American Red Cross surpassed all previous records since it took up its activities in France. During the month nine rest stations on the American lines of communication and seven on the French lines provided 408,000 meals. Nine metropolitan canteens supplied 454,000 meals. A complete new hospital with 200 beds was estab-

lished in a chateau immediately behind the front. A hospital of 500 beds is being erected near Paris. Three more dispensaries have been opened near ports. Eighty beds have been added to an American hospital near Paris, 75 at Neuilly, 100 at Military Hospital No. 1, a like number at Military Hospital No. 2, and 60 at Military Hospital No. 3. Convalescent homes have been opened at Cannes and Biarritz. Much assistance has been given to a large number of French hospitals, with special attention to those caring for American wounded. These hospitals received 2,500 surgical instruments together with an immense amount of equipment in other lines. For Americans at the front a shower bath was established with equipment for removing vermin; this has a capacity of 25,000 men weekly. In addition laundries and field kitchens have been installed in several camps, and a large quantity of tobacco and other supplies for the soldiers distributed.

Jersey City and Hoboken Hospitals Taken by the Government.—St. Mary's Hospital at Willow Avenue and Fourth Street, Hoboken, three blocks from the Government piers, is to be taken over by the Federal authorities for the sole use of military and naval patients. This will be the first complete Government hospital at the Jersey port. The 600 patients now in the hospital are being removed to hospitals in Jersey City and North Hudson. Following close on this announcement came another stating that St. Francis Hospital, East Hamilton Place, Jersey City, would also probably be taken over by the Government. Contemplating that demands may be made to turn over at least part of the City Hospital for the care of soldiers and sailors, the Jersey City Commissioners have ordered that work be rushed on an addition to that institution. The new wing will give an added capacity of 150 beds and will cost \$150,000.

Government Takes Over Sea View Hospital.—At a recent conference Health Commissioner Copeland, Mayor Hylan, and Lieutenant-Colonels Hornsby and Kramer reached an agreement whereby the Sea View Hospital, Staten Island, conducted by New York City as a tuberculosis hospital, has been taken over by the Government. The patients of the city will be moved to the city's tuberculosis hospital at Otisville, N. Y., where the army has agreed to erect additional buildings for the city. The Government will occupy the Sea View Hospital as soon as accommodations are ready for the patients at Otisville.

Clifton Springs Sanitarium Not to Be Taken.—The Government has had under consideration for some time the advisability of taking over the Clifton Springs Sanitarium for a military hospital. It has now announced, however, that the present need is not so imperative as to demand taking over the property yet.

War Department Asks Large Appropriation for Medicine.—The War Department has asked Congress for an appropriation of \$33,000,000 to provide for the medical care of the forces now under arms. This estimate is in addition to appropriations already made for the new army totaling \$130,000,000.

Women's Ambulance Corps Authorized.—Two women, Miss Ethel Langdon Drake, an American,

and Mrs. Mary E. Symonds, an English woman, arrived in New York a few days since on an unusual mission. They have come with the authority of General Petain to organize a women's corps of ambulance drivers to be attached to the Sixth French Army. Mrs. Symonds wears the Croix de Guerre and a gold medal of the Foreign Office for valorous services in driving an ambulance under fire. They claim that the need of men is far more urgent than is generally supposed and that many women can drive an ambulance as well as men. Among the qualifications necessary for women ambulance drivers are poise and capacity for individual action, together with perfect health and physical ability. Applicants must be between the ages of 25 and 35.

Gives House to Red Cross.—Jacob H. Schiff has given a house on his estate near Seabright, N. J., to the War Department and the Red Cross to be used as a rest home for nurses worn out by service at the front. The house is ready for immediate occupancy and will soon be taken over by the Red Cross.

Dr. Alexis Carrel of the Rockefeller Institute, New York, has been appointed by the French Government to the rank of Commander of the Legion of Honor. This decoration was bestowed upon him by M. Mourier, Under Secretary of State for Medical Service, in the presence of a number of noted personages.

Movable Surgical Units for American Army.—Movable surgical units such as are in use in the French Army are to be used for the care of the wounded in the American Army. These surgical units are transported on two motor trucks and contain everything needed for an operating room. The first truck contains a steam engine, which drives a dynamo for the radioscope and the electric plant and provides steam for an elaborate system of heating pipes. One side of each truck forms a sterilizing chamber in which six trays of instruments can be sterilized every half hour. The other truck carries the radio apparatus and a portable barrack for operations, together with all the appliances, also nine surgeons and physicians and thirty attendants and nurses for the staff. The surgeons work in groups of three in eight-hour shifts, so that operations can be conducted continuously. The value of these mobile units can scarcely be overestimated since the medical experience of the war goes to show that early treatment of the wounded is the vital desideratum.

Venereal Diseases in the American Expeditionary Forces.—A cablegram to the *New York Times* credits Major Hugh H. Young, Director of the Division for the Control of Venereal Diseases, with the statement that the American Army is freer from venereal diseases than any other army in the world. In making plans for this department of medical work in France, it was calculated by the medical authorities in Washington to have ten one-thousand bed hospitals in which a million men could be treated, but with 500,000 men in France there are only 500 cases of venereal disease needing treatment instead of the expected 5,000. In other words, instead of having one per cent. of our soldiers in hospitals with this class of disease the actual number is only one-tenth of one per cent.

MEDICAL RECORD.

THE VOLUNTEER MEDICAL SERVICE CORPS.

THE response to the call of the United States for physicians has been gratifying. The Medical Reserve Corps—1,400 before the war, and many of these holding commissions only by courtesy—has increased to nearly 30,000, and it is expected that 5,000 more will be added within the next year. But there are many physicians anxious to display their patriotism who are not able to serve in that body; either they are too old, have dependents, have some physical disqualification, or are performing some public service which cannot be dispensed with. The question arises, how can such men best serve? And the answer is, by joining the Volunteer Medical Service Corps.

The Volunteer Medical Service Corps is made up of physicians who would be in the Medical Reserve Corps were it not for a disqualification such as age, sex, or physical disability. No more physicians of over 55 years will be taken in the Medical Reserve Corps, for example, but they may join the other body. Many physical defects which do not hinder the physician materially from pursuing the practice of medicine may yet prevent him from becoming a military surgeon, and he can then apply to the volunteer body. Women physicians, too, will find a sphere of usefulness there. It must not be imagined that there is no standard of acceptance in this organization, or that candidates for it are not carefully scrutinized, for the reverse is true. In the first place, it must be ascertained whether or not the applicant is qualified to join the Medical Reserve Corps, and, if so, he can by no means join the other body. Just as strict an inquiry is made into the physician's professional and personal qualifications in one as in the other, and it might almost be said to be a home Medical Reserve Corps.

Many physicians who are willing to serve, and who are not able to join the Medical Reserve Corps, are anxious to know what sort of duties they are likely to get in the volunteer body, whether they will be summoned at inconvenient times, be obliged to make long trips, and so on. The fact of the matter is, the service rendered is entirely voluntary, and each man, on entering the body, is asked what work he is best suited for and to what extent demands can be made on his time. The kind of service

members of the volunteer body will probably be called upon to render may perhaps be illustrated by several examples. Thus, a physician, well known in his community as a diagnostician and internist, may live near a military camp, and the medical officers there may call him in occasionally as a consultant. Or he may be a surgeon, and be called upon now and then to do an operation somewhat beyond the skill of the military surgeons stationed in that particular place. He may be asked to render some aid in the examination of candidates for the Medical Reserve Corps, to attend the sick child of a soldier away at war, etc. In short, he is recorded by the Government as being located in that particular place, ready to help in any way he can. These calls for help are not likely to be frequent, and, before being issued, inquiry is made as to whether they are likely to inflict a hardship upon the physician or not.

Insignia have been devised for this branch of the service which have been commended by a well-known sculptor and approved by the Secretary of War. The designer, we record proudly, is a physician, Dr. Robert Dickinson of Brooklyn, N. Y. The emblem is a graceful representation of the letters V. M. S. C. above a caduceus. Instead of the trite round shape, this button is in the shape of a shield, about one and a half inches across. It is to be worn in the lapel.

The five thousand physicians who have already applied for commissions in the Medical Reserve Corps, but who have had to be rejected on account of some disqualification, such as age or physical defect, will be the first ones enrolled in this body. Next, applications will be sent to all members of leading medical societies who are over 55 years of age. And after that efforts will be made by Dr. Edward P. Davis, the chief of this organization, to enroll all the reputable physicians of the United States who cannot be taken into the Medical Reserve Corps. It is hoped that all physicians who are not able to take commissions in the latter body will at once apply for the Voluntary Medical Service Corps and do their bit that way. Only by utilizing to the last man all the medical resources of our country can our profession do its duty. The crying need of our Allies is now for doctors rather than fighting men, and we must help them as well as our own forces.

THE NATURE OF INDIGESTIBLE FOOD.

THERE is still much confusion among many minds as to the nature of food that is most likely to give rise to digestive and nutritional disturbances. Indigestible food has been taken to mean food that neither the stomach nor the intestinal tract will digest and which as a result gives rise to digestive disturbances. It is often said that the gastrointestinal tract evidences its rebellion to some foods by these symptoms. Except, however, for possible mechanical irritations, caustic effect, or blocking of the gastrointestinal continuity, no symptoms need arise

merely from the failure of digestion of food introduced into the tract. Usually such food will pass unchanged, unless through torpor of the intestinal canal it remains to ferment or to decompose. In infants whose mechanical powers are still somewhat limited, food that they cannot digest will remain to act as a mechanical irritant until expelled. Likewise food that remains to ferment and to decompose will produce symptoms from poisoning by the decompositive products. Except for these circumstances abnormal digestive conditions in infancy are caused by food that is acted upon by the digestive organs but whose products are not well borne by the immature metabolic system. But digestive disturbances are always caused by foods that by nature are digestible. Foods that are capable of digestion by the gastrointestinal ferments are also the ones most likely to suffer decomposition either in the intestinal tract, when not digested, or for some reason outside of the digestive tract before introduction therein. Ordinarily, adults do not suffer from the presence of food that is not digested and that is simply passing through the alimentary tract.

Within limits the presence of food that is not digested is good for the system because it acts as body for the fecal material and entangles within itself other obnoxious materials in its passages through and out of the body. Much solid matter of this kind often excites peristaltic action which would otherwise be dormant. The ingestion of food which by nature is entirely digestible and in consequence is also entirely absorbed is the cause of much constipation because there is not left enough residue for fecal matter. It is a mistake in the choice of food from the economical standpoint to utilize only that which has the maximum amount of food value. Much must be chosen for its non-digestible qualities. Of course, the foods that are essentially indigestible, and which have the least percentage of food value, are the woody, fibrous, tendinous, colloidal, and like substances. The nutritive content is usually a small part of the bulk of the material which contains it. In speaking of overeating it is never overeating when much indigestible material is consumed, but rather when it is digestible material that is taken in larger quantities than needed for the maintenance of the organism. So long as the digestive ferments will digest so long will the organism have the benefit of the food digested. When because of the excess of food taken in it is no longer digested it can act either as food that has no digestible qualities or it can remain to ferment or decompose and through the products of decomposition act as poison to the organism. On the other hand indigestible food is usually incapable of much decomposition and almost no excess can do harm except mechanically.

Among the foods that are essentially indigestible and which are of value in the prevention and cure of constipation are the green and fibrous vegetables, the shells of grain, fibrous capsules of fruit, etc. Meat has a great deal of indigestible connective

tissue fiber and it is for this reason that the protein value of some meats is not as high as that of some of the leguminous vegetables, cheese, etc. This liberality with indigestible foods applies only to adults. In infants almost any material may become irritating to the young mucous membrane, although in the case of older children it is essential to include some of the indigestible elements in their foods. It goes almost without saying that food idiosyncrasies occur with foods whose major portion is digestible and absorbable. Idiosyncrasies can occur only when there is absorption of the food after its digestion or decomposition.

THE SYMPTOMATOLOGY OF STAPHYLOCOCCIC INFECTIONS.

MODERN researches have shown that staphylococemia varies in its symptomatic evolution according to the age of the subject, and that two types are quite evident. The first is characterized by important general symptoms and by multiple subcutaneous abscesses or deep-seated pus collections in the cellular tissue. The second type is characterized by pemphigoid eruptions which, from their gravity, are susceptible of causing death. In the adolescent a generalized staphylococcic infection means osteomyelitis, but in the adult a staphylococemia is diagnosed with difficulty owing to the variability of the localizations of the infectious agent, the evolution of the process assuming the superacute, acute, subacute, or chronic form.

Unquestionably, to the superacute form belong deaths occurring in carbuncle or furunculosis eruptions, the organism in the primary focus possessing such virulence and such toxicity of its soluble products that secondary lesions have not the necessary time in which to develop. The onset is like that of a pneumonia with all its train of well-known symptoms, while in the acute forms a typhoid state manifests itself. In most instances a carbuncle, a batch of boils, or some other patent manifestation of staphylococcic infection will be found. At the onset the symptoms are somewhat the same as in the superacute type, but less serious. There are chills, headache, nausea, and general lassitude, while the temperature rapidly reaches 103° to 104° Fahr. The patient then looks like a subject of typhoid fever, with vomiting and diarrhea, meteorism, and enlarged spleen and liver, with occasionally a subicteric tint of the skin and scant urine containing urobilin and albumin. Dyspnea is intense and the pulse very rapid, irregular, and small. The temperature remains at about 104° Fahr., but may offer marked irregular oscillations following either a remittent or an intermittent type.

At this phase of the process death may occur, but should the organism resist, the coccus will become localized in the various viscera. Should the individual still resist with some success, multiple abscesses or suppurating arthritides appear, and an acute pyemia becomes established.

In the chronic forms of the process, with sub-

acute attacks, the lesions in the cellular or bone tissues predominate. When less serious, the infection gives rise to successive focal developments to the infectious agent, and the outcome of the case will be repeated abscess formation, covering several weeks or months in duration. In the more chronic forms, the virulence of the microbe may last for years, occurring in outbursts of the symptoms, separated by intervals of relatively good health. But the fact must not be overlooked that an increase in the virulence of the staphylococcus may arise and the case assume the aspect of the acute form with the development of various visceral lesions, which may end in death. Therefore, in every case of staphylococcal septicemia the prognosis must invariably be guarded, and although some recoveries have occurred, the number of fatal outcomes is very great. The temperature has an influence on the evolution of the process, the continued type being of more serious import than the remittent. The apyretic form is still more favorable. The prognosis is rendered very somber when pronounced adynamia is present.

The particular variety of staphylococcus has been supposed by some to be the reason for the variable virulence of this morbid process, the aureus being considered the most pathogenic, after which comes the citreus, and lastly the albus. But the visceral lesions are in reality to be held responsible, and in order of priority come endocarditis, pulmonary lesions and those of the nervous system. From the morbid traces which it leaves behind, staphylococemia lays the etiological foundation for a number of general diseases and it has been maintained that among these are arteriosclerosis and muscular atrophy.

ARSENICAL CANCER.

ARSENIC has been on several occasions an object of suspicion as an exciting cause of cancer. At first sight, the suspicion seems to be based on sound premises, or, at least, not to be devoid of reason. Taken in considerable doses for a protracted period, arsenic irritates the mucous membranes as well as the skin, moreover, producing a watery discharge from the eyes and nose and a brown discoloration of the skin. Now, it is generally believed that constant irritation is an exciting cause of the localization of cancer, and many cases have been cited in support of the contention. It has been further suggested that the habitual ingestion of highly spiced foods and the continual consumption of alcohol in the form of spirituous liquors may play a part in the localization of the disease. Therefore, the idea is by no means far fetched that arsenic, which is an irritant, may act similarly. The matter is discussed in a paper read before the London Dermatological Society, by Dr. Charles E. de Silva and published in the *Medical Press*, March 27, 1918. De Silva is inclined to scout the view, although he allows that there are some grounds for it. He is of the opinion that if arsenic had any tendency to cause malignant degeneration of the skin on which it acts as an irritant during its elimination, after

circulating through the tissues and glands which absorb so much of it, cancer is more likely to occur chiefly in the stomach, intestines, and liver, as the result of direct primary irritation during its absorption in much larger quantities than is eliminated by the skin. The breast, skin of the head, face, and neck, the lips, mouth, and uterus should be particularly liable and not escape. But there is no proof of the development of arsenical cancer in these specially liable parts of the body. Yet another strong argument against arsenic being the cause is the fact that cancer has not been reported as a common sequel of chronic arsenical poisoning among drinkers of arsenical beer, or in diseases where it is administered in gradually increasing doses for long periods, as in chorea, pernicious anemia, malaria, lymphadenoma, epilepsy, asthma, etc. In short, the evidence against the supposition that arsenic is an exciting cause of cancer in the human subject is weighty if not actually convincing. The conclusion then reached by de Silva is that arsenic is only responsible for the production of the keratotic condition, or preparation of the favorable "soil"; in other words, determines the localization of the disease.

News of the Week.

Traffic Rules for Physicians.—The first of several new traffic regulations planned by Deputy Commissioner John A. Harriss became operative in this city on May 15. This ordinance authorizes the issuance of special cards to physicians, which will permit their motor cars to stand in crowded streets when on urgent medical calls.

New York City's Water Supply Protected.—A bill has been signed by Governor Whitman creating the Mohansic Lake Reservation from the territory upon which the State had formerly planned to maintain a hospital for the insane and a reformatory for delinquent boys. This finally disposes of a proposition to risk contamination of the water supply of New York City that has for the past five years been a subject of debate and of legislation. This fortunate outcome of the affair is largely due to the efforts of the Merchants' Association, which has always vigorously opposed the erection of these institutions on the New York watershed.

To Reopen Children's Infirmary.—A meeting was recently held at the home of Mrs. Philip M. Lydig for the purpose of initiating a campaign to raise a fund of \$200,000 for the New York Infirmary for Women and Children, which was forced to close its doors last March because of lack of funds. Addresses were made by Dr. Simon Flexner, Dr. Willy Meyer, Dr. S. Josephine Baker, and Dr. Samuel W. Lambert. Emphasis was laid on the special need of caring for women and children during the period of the war.

German Invents Drug to Dull the Edge of Hunger.—The Berlin newspapers of recent date contain advertisements by a German chemical firm of a newly invented preparation which, "though not forming a substitute for the minimum daily sustenance, is an excellent preparation for stilling premature hunger, and enables one to hold out until the next meal time."

Industrial Conference Urges Disease Preven-

tion.—The National Industrial Conference Board, which met in Boston on May 12, presented a report on "Sickness Insurance and Sickness Prevention" which urges the prevention of disease wherever practical, rather than compensation for losses incurred by sickness. The report says: "To fail to apply preventive measures to such illnesses, disabilities, or conditions as will almost certainly respond, and instead to permit them to go uncorrected until the victim becomes a charge on society is absurd. Certainly if the State can contribute to the support of the individuals after they become incapable of caring for themselves, it can contribute to prevent them from becoming incapacitated."

Government Urged to Take Up Public Health Problems.—The National Industrial Conference Board has been studying the question of public health, and has compiled data on the prevalence of sickness among the American people. A report which this organization has submitted claims that of every 100 residents of the United States at least one is afflicted with tuberculosis, and a larger percentage with organic heart disease. General Crowder makes the statement that of 2,500,000 men examined for military service 33 per cent. were found physically unfit. An investigation by the Public Health Service, with the authority of Congress, is proposed, and the annual physical examination of all persons urged to determine on a course of prevention. The report submits the result of surveys made in ten typical communities in the North and South showing that on an average 2.02 per cent. of the population were sick and 1.88 per cent. were unable to work. The statement is made that there are at least four feeble-minded persons in every 1,000, and that feeble-mindedness is responsible for from 25 to 50 per cent. of the inmates of our prisons and jails, and that from 15 to 30 per cent. of the inmates of almshouses are feeble-minded. The conclusion drawn is that the highly successful results of prevention in certain of the common diseases justifies Federal action along this line.

New York Health Drive.—The Health Commissioner announces that the health drive which the New York City Health Department is planning will begin on May 26 and will last a week. The purpose of the drive will be to rid the city of all rubbish piles and dump heaps and unsanitary accumulations due to neglect and carelessness.

Special Child Welfare Meeting.—A special meeting of the Section on Pediatrics of the New York Academy of Medicine was held on the evening of May 17, which was devoted to a consideration of the subject of Child Welfare Work in France. Dr. Pierre F. Armand-Delille, major in the Medical Corps of the French army, delivered an address in which he reviewed the history of child-welfare work in France and told what was being done at the present time in the way of child-welfare work and the care of mothers. Dr. William Palmer Lucas, director of the child-welfare work under the Red Cross, in France, described the work that the Red Cross was doing for the women and children of France, illustrating his talk with motion pictures and lantern slides. Dr. Herbert B. Wilcox presided at the meeting.

Dr. Antoine Depage has arrived in this country, and will attend the meetings of the American

Surgical Association in Cincinnati and the American Medical Association in Chicago.

Dr. Benjamin T. Terry has resigned his position as director of the Brooklyn Laboratories of Pathology.

Dr. Geza Kramer has been appointed Medical Superintendent of the Sea View Hospital, Staten Island.

Dr. S. Dana Hubbard of the department of epidemiology has been appointed to take charge temporarily of the Bureau of Public Health Instruction of the New York Department of Health made vacant by the resignation of Dr. Charles F. Bolduan.

Gifts and Bequests.—The United Hospital Fund has distributed \$150,000 among the hospitals of this city on the basis of the actual free work done by each hospital. This is \$35,000 more than has ever been distributed before. The Montefiore Home received the largest share of this fund, \$13,406, and the Mount Sinai Hospital the second largest share, \$11,457. The women's auxiliary to the fund announced that it had contributed \$29,500 as the result of a special appeal showing the necessity of continuing hospital work at this time.

The Long Island College Hospital, as residuary legatee, receives \$265,944 as its share of the estate of the late Charles W. West.

New Competitive Examination for Chief Medical Examiner.—The Municipal Civil Service Commission of New York City has voted to cancel the existing eligible list for the post of chief medical examiner, which pays \$7,500 a year. A new examination will be held, and the present incumbent of the office, who is holding the place under a temporary three-months' appointment, will have to take the examination again if he desires to become a permanent candidate for the office.

Medical Society Elections.—The MICHIGAN MEDICAL ASSOCIATION, which held its annual meeting at Battle Creek, on May 7 and 8, elected the following officers: *President*, Dr. Arthur M. Hume of Owosso; *First Vice-President*, Dr. W. Sam Shipp of Battle Creek; *Second Vice-President*, Dr. C. C. Miller of Cadillac; *Third Vice-President*, Dr. J. C. Chester of Emmett; *Fourth Vice-President*, Dr. F. W. Garber of Muskegon.

The SOUTH ESSEX (MASS.) MEDICAL SOCIETY, at its annual meeting at Nahant, on May 7, elected the following officers: *President*, Dr. James J. Egan of Gloucester; *Vice-President*, Dr. Carolus M. Cobb of Lynn; *Secretary*, Dr. Hamlin P. Bennett of Lynn; *Treasurer*, Dr. George Z. Goodell of Salem.

Obituary Notes.—Dr. ALFRED LYNDON JACKSON, a graduate of New York University Medical Department, in 1897, died at his home in New York City, May 12.

Dr. THOMAS HOLLINGSWORTH ANDREWS died at Philadelphia on May 8 at the age of 75 years. He was graduated from Jefferson Medical College in the class of 1864. During the Civil War he served with the Sanitary Commission and later as assistant surgeon in the United States Army. He was intern to the Pennsylvania, Episcopal Philadelphia and Charity Hospitals. He was for a time chief of the Surgical Clinic at Jefferson Hospital and demonstrator of surgery and of anatomy in the college. He served two terms as Coroner's Physician. He was professor of anatomy in the Wagner Free

Institute of Science. He was surgeon to the outpatient departments of the Pennsylvania and Howard Hospitals. He had been a Fellow of the College of Physicians of Philadelphia, a member of the Philadelphia County Medical Society, of the Medical Jurisprudence Society, of the Pathological Society of Philadelphia, of the Philadelphia Obstetrical Society, of the Philadelphia Academy of Natural Sciences, of the Medical Society of the State of Pennsylvania and of the American Medical Association.

Dr. FRANK JUDSON BARDWELL died at Tunkhannock, Pa., on April 14 following a surgical operation, at the age of 50 years. He was graduated from Yale University School of Medicine in the class of 1891. He was a member of the Wyoming County Medical Society and of the Medical Society of the State of Pennsylvania and a Fellow of the American Medical Association.

Dr. DAVID GILBERT YATES died at his home in New York City on May 10, aged 48 years. He was a graduate of the New York University Medical School, in 1898, and at the time of his death was visiting surgeon at the New York Eye and Ear Infirmary and attending physician at the Manhattan Eye and Ear Hospital. Dr. Yates was a member of the American Medical Association, the American Laryngological Rhinological and Otological, the New York Academy, and other organizations.

Dr. MARTIN FLEMING, who retired from the practice of medicine some years ago, died at his home in New York City, on May 11, aged 71 years. He was a graduate of the College of Physicians and Surgeons, New York, and for many years attending physician at Bellevue Hospital. Dr. Fleming was a member of the New York Academy of Medicine and of the Medical Society of the County of New York.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

NATURAL SCIENCE IN THE EDUCATIONAL SYSTEM OF GREAT BRITAIN—A STATE DENTAL SERVICE—THE RADIUM INSTITUTE—FEEDING OF LABORATORY ANIMALS—BOTULISM(?)—DEATH OF PROF. MICHELL CLARKE.

LONDON, April 25, 1918.

A COMMITTEE was appointed in the summer of 1916 by Mr. Asquith, then Prime Minister, to inquire into the position of natural science in the educational system of Great Britain. The reference of the committee was especially to that position as evidenced in the curricula of secondary schools and universities, and the members were asked to advise—though not in so many words—what measures were needed to promote the study in these institutions of such obviously neglected subjects as chemistry, physics, and the natural phenomena of geography, astronomy, and climatic conditions. That it was intended to elucidate from a carefully chosen body of experts advice possessing practical bearings was shown by the fact that the committee was asked, while paying due regard to a liberal education and the claims of pure science, to direct their counsels specifically to the relations which ought to

exist between science in its application and all industries and professions. The committee was presided over by Sir J. J. Thompson, the famous physicist, who is both president of the Royal Society and master of Trinity College, Cambridge, and the notable medical members of the body are Dr. Henry Head, the well-known neurologist, and Prof. E. H. Starling. The committee have rendered a valuable and practical report, the first of whose principal conclusions is that natural science should be included in the normal course of the school education of all boys and girls up to the age of about 16, and that periodical inspections should be made of all schools to see that the courses are maintained at such a standard that they could be accepted as a qualification for entry into the professions. With special reference to the medical profession it is recommended that a "First School Examination" should be instituted at which all candidates should be required to satisfy examiners in both mathematics and science, adding that this examination ought to be recognized by the General Medical Council as qualifying for entrance to the medical profession. This recommendation has more far-reaching significance than appears on the surface, especially if the General Medical Council could find means to make such a First School Examination compulsory upon all intending medical students who have not passed some obviously more stringent test. For at the present moment the commencement of the medical curriculum proper may be anything from full graduation at Oxford and Cambridge, or the passing of such difficult tests as those exacted in the Matriculation of the University of London, down to the inadequate examinations held by the College of Preceptors or by certain Royal Corporations. A First School Examination, the passing of which would, by one single standard, admit all students to all professions, would be a real blessing to our over-examined youth. A further recommendation with regard to the relation of science to medical education is one suggesting that medical students should be allowed to take their "First Professional Examination," which generally implies a knowledge of a certain amount of chemistry, physics, and biology, before entering the medical school. In this way no student would join a medical school until he was ready actually to go to the strictly professional subjects of anatomy, physiology, and the biological or pharmaceutical developments of chemistry. Now the legal duration of the medical student's education in Great Britain must be at least five years, and at the present time one year of this period (generally more) is consumed in the study of chemistry, physics, and biology. Two more years are usually required for the mastering of anatomy, physiology, and pharmacology, in the first two of which subjects our examiners are always exacting, leaving only two years for the acquisition of all clinical knowledge, both theoretical and practical, if the student is to qualify in the shortest legal period. It is needless to say that although the law says that no medical student shall become a qualified practitioner in less than five years, circumstances make it almost inevitable that over six years will be fully taken up by the student's education. Indeed, I believe the average duration of studentship is little short of seven years. Undoubtedly the length of the

curriculum, as dictated by the pressure of study and not by the terms of the Medical Acts, presses hardly upon the purses of parents and guardians who have to support the students, and permission to take the first professional examination before entering a medical school would be a great boon to many, but the great awkwardness is that the boon would not be universally distributed. There are all over the United Kingdom not a sufficient number of schools providing adequate instruction in chemistry, physics, and biology, to enable their pupils to pass tests in these subjects. Notably in unlucky Ireland the secondary schools are few and bad. The permission to take the first professional examination before entering a medical school would therefore be valid only for some students, not for others, as many lads, for lack of opportunity, would be compelled to resort to their medical school for their instruction in the preliminary ancillary subjects, and they would not save the year of medical education which would be saved by those more fortunate in making an early start. But the General Medical Council is a standardizing body for the whole country, and cannot make by-laws which do not bear with equal force upon all students alike. So that this valuable recommendation of Sir J. J. Thompson's committee—and it is a most valuable and practical one—will not be adopted without considerable difficulty.

The examination of recruits has led to a general eye-opening as to the condition of the teeth of our country, and it is not surprising to find a scheme for a State dental service designed to meet what is evidently a State default. Such a scheme has recently been codified by Major F. W. Broderick in the columns of *Public Health*, and his proposal to meet existing ills by the creation and distribution among the population of "dental units" composed of dental surgeons and dental mechanics, as far as they go, are sound. Undoubtedly in this way the present position would be improved, but our widespread dental troubles require the interference of preventive medicine. A State dental service should form part of a general State medical service to be of lasting benefit, and the bigger idea is still in the stage of ideas.

A report of the work carried out at the Radium Institute under the medical superintendence of Capt. A. E. Hayward Pinch has just been published with the authority of the Executive Committee of which Sir Frederick Treves is the chairman; and within the limits of the work it is an extremely satisfactory document. To form an adequate judgment of the results of the activities of the Institute it is important to remember that operable cases of malignant disease, rodent ulcer alone excepted, are as a rule declined, though the rule is waived in instances where patients have absolutely refused to submit to operation. The feature of the report is the inclusion of the history and records of patients whose treatment began seven or eight years ago, so that when prolonged relief (one would like to say "cure") has been the apparent result, there is evidence from which to judge the value of the claim. The term "apparent cure" is used throughout the report in relation to cases of malignant disease as representing a condition in which all traces of the original lesions have disappeared, in which there is

no sign of any recurrence, and in which the patient as far as can be determined by thorough and careful examination is free from any indication or symptom of the disease. It will be admitted that the limitations imposed upon the words "apparent cure" lean to the side of severity. A summary of cases during the year 1917 showed 241 improved cases, 104 not improved, 69 apparently cured, and 22 cured. Forty-eight were examined, but for some reason or other not treated. Twenty-eight voluntarily abandoned treatment during the course, while there were 44 deaths. As bearing on the charitable side of the Institution it may be mentioned that of the 6,000 separate treatments administered during the year, over 4,000 were given to necessitous patients free of all charge. Among the conditions where the most good seems to have been done may be mentioned epitheliomata of the vulva, early carcinoma of the uterus, rodent ulcer—of all forms of malignant disease this is the one which is most amenable to radium treatment—and various forms of sarcoma. Mediastinal tumors have also benefited by treatment at the Institute, notable results having been obtained in patients who have presented themselves suffering from dyspnea and orthopnea, accompanied by severe venous congestion and disturbances of the sympathetic and recurrent laryngeal nerves. It is probable that the majority of these growths were lymphosarcomata. Keloid, lupus erythematosus, lichenification of the skin, and nevi have all improved under the treatment. The number of patients suffering from carcinoma of the breast applying for treatment exceeded during the year that of any other sufferers from malignant disease, but as the patients in whom operation is practicable are invariably advised to have recourse to surgery, it follows that those treated at the Institute were, as a rule, in a very advanced state of disease with extensive lymphatic involvement. In some of these cases, however, good results have been obtained, often in complete contradiction to carefully made surgical predictions. The report is of value in two directions, for on the one hand it shows how much practical good may follow the intelligent use of radium, and on the other it is a frank confession that we have in radium no magical cure of cancer. And that is the position which is too often attributed to radium by the lay press, to the profound disappointment of many sufferers.

Under the Defense of the Realm Act, the Ministry of Food has sanctioned the acquisition (notwithstanding any preventive legislation) by those who are licensed to carry on medical research by animal experimentation of foodstuffs necessary for the animals in question. Every licensee is required to keep a record of the quantities of food he so acquires.

Three epidemics, having almost exactly the same association of symptoms, have recently broken out respectively in the north and west and later in the south of London, and in the district of Sheffield, while a disease possibly of the same nature has also manifested itself in Paris. The obvious symptoms are an acute ophthalmoplegia associated with asthenia and other nervous manifestations. The first outbreak, which occurred at the end of March, and to which I have already referred, was apparently scattered over the north and west of London, and

seven cases fortunately came, almost as a group, under the attention of Dr. Wilfred Harris, physician to St. Mary's Hospital and neurologist to the Third London General Hospital. The first of these cases was an officer under the care of Captain Sir John Broadbent at the hospital, who called in his neurological colleague for consultation. All the seven cases were profoundly ill and had certain features in common; namely, an incubation period of under twenty-four hours, a distressing collection of mucus in the nasopharynx owing to disorder of the buccopharyngeal glands, ophthalmoplegia externa and interna, and various gross disarrangements of vision. All presented, as well as dysphagia and aphonia, disturbances of the circulatory and respiratory systems, indicative of bulbar paralysis, and five had retention of urine. In only one of the seven cases was there actual paralysis of swallowing. Of these seven cases one proved fatal when no obvious changes were found post-mortem. In the case of the officer first seen an organism was grown from the stools and urine resembling in morphological characteristics the *Bacillus botulinus*. Almost simultaneously a series of cases presenting analogous features came under the attention of Dr. Arthur J. Hall, Professor of Medicine at the University of Sheffield, and Physician to the Sheffield Royal Hospital. Professor Hall's cases at first sight were divisible into meningitic and asthenic types, and the unusual clinical picture presented led to inquiry into some common origin, with the result that cold, trauma, ear disease, rheumatism, syphilis, diphtheria, and cerebrospinal disease were all eliminated. Professor Hall saw that it was reasonable to connect the cases with some poisonous elements in the food or some deficiency of essential ingredients, but on investigation obtained little evidence to support the theory. At this time, however, his attention was called to the cases which had come under the care of Captain Wilfred Harris, with the result that the similarity between the Sheffield epidemic and the form of poisoning due to the consumption of food infected with the *Bacillus botulinus* became clear. This week the medical officers of the Lambeth Infirmary admitted a series of cases suffering from an epidemic disease of obscure origin, all showing signs of toxic bulbar paralysis, several of whom had been diagnosed before admission to the institution as polioencephalitis. In these cases the condition was almost similar to the meningitic type described by Major Hall, the symptoms of bulbar paralysis and meningitic irritation predominating. Simultaneously a case closely resembling those described by Captain Harris was reported to the *Lancet* by Leonard Dobson and an account of another case was contributed to the same journal by Dr. Farquhar Buzzard, who declined to describe his patient as suffering from anything more definite than "toxic encephalitis." With regard to the attribution of these cases to the action of *B. botulinus* on other than clinical grounds in the first case which came under Captain Harris's attention, the symptoms commenced after meals of sausage and lobster, while one of Professor Hall's patients definitely attributed her symptoms to tinned food. It is obvious that in all cases admitted to general hospitals or infirmaries in England at the present time there will be great probability of their having eaten

tinned food, and the action now taken by the local Government Board is, therefore, very reasonable. For Dr. A. W. J. MacFadden has issued from the Board a request to all medical officers of health, having such cases brought to their notice that they should send to the Board full particulars with regard to food history, the Board having at the same time made arrangements to examine for those officers any samples of food material which they have good reason to suspect is the origin of any of the cases. In Paris the epidemic has occurred chiefly among children, and it would not be safe to assume we are here dealing with the same condition until the *B. botulinus* has been discovered either in portions of food actually eaten by the patient, or through one of the usual methods familiar to bacteriologists. It will be taken for granted that the authorities in the United States are equally alive to the possibilities with which they may have to deal, for in one case at least the symptoms followed upon the use at table of tinned meat prepared in the States. But it must be allowed that Dr. Farquhar Buzzard's caution in not assuming that *B. botulinus* is a common cause of these cases has sound scientific reason. There is nothing like a consistent story in any proportion of the cases of the symptoms having followed from the eating of tinned food. *B. botulinus* implies, translated literally, that the sausage is the usual medium, but all tinned food and potted meats may shelter the bacillus. This reference to the exact meaning of a classical word reminds to mention the drole error into which the English lay press was betrayed in an attempt to introduce the subject to their readers. Some of the best daily journals described the cases as "vulvar" paralysis.

The death occurred recently of Dr. John Michell Clarke, professor of medicine and acting vice-president of the University of Boston. Professor Clarke was one of the best known provincial neurologists in the country. He contributed freely to Allbutt and Rolleston's "System of Medicine" and to Quain's "Dictionary of Medicine," to *Brain*, the *British Medical Journal*, and the *Lancet*, writing always from the clinical point of view as a thoroughly practical therapist as well as academically learned. Professor Clarke was 58 years of age, and seemed to have a long course of usefulness still before him, and his death is a real loss to medicine.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

THE UNIVERSITY UNION IN PARIS—SUPERSTITION IN THE TRENCHES—CHAIN OF HOSPITALS BEHIND THE LINES—SCIENTIFICALLY FEEDING THE NATIONS.

PARIS, April 8, 1918

EARLY in the summer of 1917 there appeared in the daily papers evidence that certain graduates of the larger American universities residing abroad were moving to unite their members into some sort of a social organization, to meet at least once a year at a dinner, to keep the members in touch. Growing out of this movement sprang the idea of organizing all of the American colleges and universities into an union, centered in Paris, which now has its headquarters in the Hotel Royal Palace, at 8 rue de Richelieu. With the first notice of an endeavor to

organize the separate institutions, the writer thought it a good idea to try to bring the members abroad of the New York University together and took the matter up with Chancellor Elmer E. Brown, who favored the project, which is about to be put into execution, and this university will doubtless become also a member of the University Union.

The movement has developed so rapidly and met with such instant success that recently Mr. Anson Phelps Stokes, chairman of the American Board of Trustees, came to Paris to give it personal attention and assistance. Mr. Stokes is not only the present chairman of the American Board, but he is the founder, the original prime mover, of the enterprise. Mr. Stokes is secretary of Yale University. All American university men in France welcome him informally, as the French university authorities have welcomed him formally. He comes to inspect and encourage the union, which now numbers more than 100 American institutions. Its directors in Paris have done admirable work. Professor Nettleton of Yale and Professor Lansing of the Massachusetts Institute of Technology are backed by a Paris executive committee which represents in addition four other great universities, and an advisory council of twenty-four from many additional institutions.

It is well that such a cooperative establishment should bring to the attention of the French the real variety and the fine rivalry of American institutions of learning. Hitherto little has been known of this. The Harvard exchange professorships and the generous activities of certain Harvard men living in Paris have served to link the name of Harvard with American higher education; while other great and ancient institutions such as Yale and Princeton and the flourishing State universities of Virginia, Michigan, Wisconsin, California, the newer graduate foundations, Johns Hopkins and Clark, have been names hardly known beyond professional circles. Harvard has deserved her fame. But recent events are bringing out the name and fame of others of our famous seats of learning. Princeton, for example, claims the President of the United States; her own president, John C. Hibben, has been one of the pioneers in the education of the United States in the questions of the war, and one of the two resident American members of the Institute of France hails from Princeton.

I understand that the union is preparing plans for a permanent establishment for students in Paris after the war, which will not only provide a "hospice" for American students here, but through its splendid organization in the United States attract to France the multitudes of young men and women who aforetime went to Germany. It is to be hoped these plans may be fully realized, and all the agencies working to this common end may rally about its administrators, bidding them continue their good work.

A more superstitious lot of men than the soldiers who are fighting for civilization on the western battle front could not be found. The professional baseball player in America has "nothing on" the Allied soldiers. There isn't a soldier among the millions who won't balk at lighting the third cigarette from the same match. The boys smile at their own child-

ishness or whatever one wishes to call it, but nevertheless they say they will "light another match, even if matches are scarce."

But there is another superstition which is taken far more seriously. The soldier who goes "over the top" the first time after he has had a leave does not expect to return. Any British, French, or American soldier will give you the names of his friends who were killed the "first time over" after coming back from a furlough. And so it happens that, notwithstanding the hardship of the life at the front and the keen appetite the enlisted man has for a few days' tranquillity and security, tens of thousands of soldiers decline to accept a leave. They don't like this "over the top" when they return. Before they have had leave they don't mind—that is, they don't exactly mind—but it is indeed with many misgivings and unquestionably a weak heart that they go over when they come back from leave. There is another phase to this superstition which has deeply engraven itself upon the minds of the soldiers. If a soldier "trades leave" with another, he, the man who proposed the trade, is marked for death the first time he "goes over." An Australian who has been at the front since the first battle of Ypres says that he has known fourteen Australians who were killed after they had traded leave.

In the midst of constant death it is perhaps the most natural thing in the world that there should be superstitions among the soldiers. There are some more sacred than others about which the boys hesitate to talk. If a letter from a mother arrives on the day a raiding party is sent out the members of the party—particularly the man who received the letter—are liable to be captured. Strange deduction this, but the men have plenty of time for sombre thinking and introspection. A man from Queensland has constantly in his pocket a sixpence which was given to him in Australia by a young woman. It has a hole in it. He says he knows it is his keeper. "I wouldn't lose it for all the money in England," he says.

Dr. John C. Baldwin of Johns Hopkins Hospital, Baltimore, is in Paris for the moment, having recently returned from Evian, where he has been temporarily directing the two hospitals of the American Red Cross in connection with the service of repatriation. Dr. Baldwin says that at the present time eleven convoy trains arrive weekly from Germany, via Switzerland, each bringing about 650 repatriates.

The work for children repatriated from behind the German lines is only one of the services of the Red Cross for the civilians of France. With the establishment of two health stations at Amiens, to which Dr. Baldwin is soon to set forth, there will be completed what amounts to a chain of hospitals stretching back of the lines practically across the entire map of France. The surgeons at one of these health stations will be in contact and consultation from time to time with the staff of the nearest hospital, and that staff will be in communication with the next nearest, and so on, so that this chain stretches from Amiens to Nesle, from Nesle to Grécourt (where is the Smith College unit, recently incorporated with the American Red Cross), from Grécourt to Blerancourt, where Red Cross work is in collaboration with the American

fund for French wounded, from Blerancourt to Chalons-sur-Marne, where the A. R. C. and the Friends are working hand in hand, and from Châlons to Toul, the center of a network of dispensaries held weekly in the various villages nearby. This idea of neighborhood clinics radiating from a field base and made possible by the omnipotent Ford, which enables a small staff to reach a relatively large and scattered population, is a new factor in public health work, French or American.

Work for the civilian population on very much the same lines as the Red Cross follows at Nesle and at Toul and is operated by United States army surgeons throughout the American zone, which completes the chain.

There was recently held at the Paris Faculty of Medicine on Inter-Ally Conference to study the question of the scientific feeding of the Allies. It was presided over by Mr. Victor Boret, Minister of Agriculture and Supply, assisted by M. Vilgrain, Under-Secretary of State for Supply. The conference is composed of professors of the Faculty of Medicine and of technicians delegated by Great Britain, the United States, France, and Italy. In opening the conference, M. Victor Boret made some important remarks. He said in sum: The Ministers of the Allied nations recently assembled in London decided to bring about this scientific conference with the object of studying the conditions by which it is possible to obtain the best results from the very limited resources which the Allies possess for their alimentation, and to share them out judiciously, taking into account the considerations dictated by physiology and political economy.

The chemical composition of foods and the study of food rations will serve as a basis for the work of the conference, with the object of the measures to be taken to assure sufficient alimentation for the population of each country. The conference will also occupy itself with the feeding of animals, particularly those which contribute in furnishing part of the food of men. The object of the conference is to proportion the stock of food to the needs of all, and to do this it must consider the general resources of each country and ascertain whether, when combined, there will be the quantity needed. When sharing these resources account must be taken of the conditions and habits of these countries, in order to avoid any useless change. For example, in regard to the distribution of wheat it must be taken into consideration that France is the country where normally the greatest quantity of bread is eaten. In the present circumstances, each individual in each country must reduce his requirements to a minimum and reduce his consumption.

This problem can be solved only by method in the use of food and human labor. To obtain the greatest benefit from our limited resources we must sacrifice normal food rations to scientific rationing, seeking to obtain from each individual the best working results with a minimum alimentation, just as the maximum of motion with a minimum of fuel is required from a well regulated machine.

The American delegates to the inter-Allied Scientific Conference on Supply are Professor Russel H. Chittenden of Yale, Professor Graham Lusk of the Cornell Medical School, and Mr. John Lawrey Simpson, delegate of the Food Administration.

Progress of Medical Science.

I. Meningococcus Carriers: Preliminary Report from First Naval District.—William R. Redden presents the results of an investigation into the question of meningococcus carriers in the first naval district. Such carriers were isolated on the basis of agglutinations in 1/10 or 1/50 dilutions of polyvalent antimeningococcus sera on slides, followed by gross agglutinations in tubes, the final readings being taken after twelve hours in the incubator at 55° C. and twelve hours in the ice box. Over three thousand cultures were examined, three hundred of which were positive. Of this group about 40 per cent. agglutinated specifically in 1/10 antimeningococcus serum, and about 60 per cent. as high as the 1/50 dilution on the slide. It was found that results of gross agglutination in tubes rarely altered the positive findings obtained on slides. Repeated examinations of a group of one hundred carriers showed that only 16 per cent. were ready for discharge at the end of the minimal isolation period of twenty-one days; that 7 per cent. remained positive over forty days; that 6 per cent. showed positive cultures after three successive negatives; that 49 per cent. showed positive cultures after one or more negatives, thus demonstrating a persistent and intermittent type of carrier; and that a carrier may show a pure culture on one examination, on the next day only a few scattered colonies in a mixed culture, and on the third a pure culture of meningococci. Treatment was of no value. A sharp decline in the number of positive cultures from the carrier group was noted during two weeks of warm weather. From a study of thirteen groups of "contacts" and six groups of "non-contacts" the author arrived at the following conclusions: Under good hygienic conditions groups of naval men, if only moderately well selected on the basis of possible contact with a known case of cerebrospinal fever, show from 6 to 8 per cent. carriers. Under poor hygienic conditions such groups may show from 17 to 22 per cent. carriers. Among groups of naval men well selected on the basis of possible contact with a case of cerebrospinal fever, and living in close contact with each other, 20 to 35 per cent. appear to be carriers; but when only a small group of guards, isolated from the rest of a crew, is considered, only 11 per cent. are positive. One group of one hundred men taken at random from a camp where there had been no case of cerebrospinal fever, and where living conditions are excellent, showed 9 per cent. carriers as contrasted with 25 per cent. which appeared in a group of one hundred taken from overcrowded barracks where a number of cases had occurred, and where from 20 to 25 per cent. carriers had been found on previous examinations. In another non-contact group of seventy-nine men representing a naval student body living in barracks under good hygienic conditions 9 per cent. were carriers as contrasted with the 1 per cent. found among one hundred women students of Simmons College and the first and second year Harvard medical students. The author points out that the important factors in the increase in carriers from 1 to 2 per cent. among civilians to 20 to 35 per cent. among recruits, are: contact with known cases of cerebrospinal fever; unhygienic conditions such as come from crowded barracks; severe physical labor, coupled with exposure to extremes of heat and cold, and, finally, contact with carriers of meningococci.

1. **A Bacteriological Study of Cigars.**—Randle C. Rosenberger has made a bacteriological study of 118 cigars, taken from twenty-eight different stores where they had been, in many cases, exposed to the air and dust of the store, and from the pockets of individuals. Most of the cigars were of popular brands, which sell at 5 or 10 cents each. Cultures were made from the mouth end of the cigar as soon as possible after purchase, and in some cases tobacco was taken from the center of the cigar and placed in the sterile bouillon. Without exception abundant bacterial growth was demonstrated within twenty-four hours. Spreads were made from the cultures and were stained with methylene blue and by Gram's method. In the majority of instances spore forming organisms developed, among them being *B. mycoides*, *B. simplex*, *B. cohenrens*, *B. subtilis*, *B. megatherium*, *B. albolactis*, *B. mesentericus fuscus*. Streptococci were found in four instances, but were not obtained in pure culture. *Staphylococci albus* and *aureus* were isolated in pure culture in fourteen instances, but guinea-pig inoculation produced no lasting effects. A small motile organism resembling *B. coli* in morphology was found in cultures from twenty-five cigars, but only two gave indol production and fermented various sugars. Cocci resembling the gonococcus were obtained from a cigar taken from the pocket of an individual. The bacterial flora were just as abundant in the case of cigars wrapped in paper or in tinfoil; and in cultures made from the inside of the cigar, the spore-bearing organisms were more abundant than nonsporiferous bacteria. Rosenberger points out that though no virulent pathogenic or pyogenic organisms were demonstrated, the occurrence of staphylococci makes it evident that the practice of moistening the end of cigars with the mouth or tongue, or twisting the end with the moistened fingers should be forbidden—a practice which certainly exists in the small manufacturing plants; and that the selection of individuals for making cigars should be just as strict from the point of view of skin diseases, tuberculosis, etc., as in the case of waiters or dairymen. He also suggests that the end of the cigar should be clipped with a cutter and not bitten.

8. **Immunization Against Colds.**—J. G. Dwyer points out that the most potent general cause of colds is intestinal poisoning of a chronic nature, which leads to an alteration of the vasomotor control, with the possible addition of a local cause to keep this active. Local causes may be divided into two classes, malformations of the nose, and chronic disease of the frontal sinuses; then there is the cold which is simply the manifestation of a general condition, such as grippe. The ordinary cold in the head is most often due to bacterial infection. These bacteria usually run in groups; the author has found them in normal nose strains of *Bacillus mucosus capsulatus*, pneumococcus No. 4—pathogenic for white mice—*Micrococcus catarrhalis*, and the various strains of cocci—such as the *Streptococcus hemolyticus* and the *Staphylococcus aureus* and *albus*. Very often two or more of these are found, or one in pure culture, and the question arises whether these are present simply as saprophytes or are capable of producing disease under favorable circumstances. During a cold cultures from the secretion, even on the richest media, are frequently negative. The explanation of this may be that the bacteria are destroyed by the acidity of the secretion except at points high up in the sinuses, where it is impossible to get a culture, or it may be that the lesion is caused by a filterable virus. The fact that Tuncliffe was able to produce a typical acute coryza by inoculating herself with such a virus would seem to lend color to the latter theory. The difficulty of isolating the influenza bacillus may also have some bearing upon this. Dwyer states that immunization against colds is feasible, and in some of his cases it has lasted for two years and more. Subjects, however, must be carefully chosen so as to exclude those who from some local or general cause would be likely to develop repeated colds, when failure which was due to such cause might be wrongly ascribed to the vaccine. Very poor results were obtained from the administra-

tion of vaccine to those suffering from or developing a cold. In administering the vaccine the author's procedure was as follows: The patient's nasal flora was investigated and a vaccine prepared of the organisms found, with the addition of some freshly isolated strains of the more common organisms. (The method of taking the culture is important. It is best to take same from the nasopharynx if possible, and if any sinus disease is present cultures should be taken from there.) The immunization should be carried on for quite a long period; the author's practice has been to give about 15 or 20 doses at intervals of five to six days. He has treated about forty patients in this way, and is favorably impressed by the results obtained.

2. **The Cause of Lumbar Puncture Headache.**—Russell G. MacRobert suggests a new factor as a cause of lumbar puncture headache. He points out that to obtain fluid by puncture the dura and the arachnoid must be pierced. A visit to the operating or post mortem room will soon convince one that a puncture in the rigid dural membrane, unlike that in a vein, usually persists as a clean-edged round hole, and since the spinal fluid is always under some pressure in its sac what is there, he asks, to prevent a continuous leakage into the epidural space of the spinal canal, following the extraction of the needle? MacRobert has become convinced that closure of the puncture hole usually takes place when the arachnoid tissue, as it drops from the point of the departing needle, is swept against the dura mater, by the pressure of fluid within. In this way the dural hole is blocked by an intact area of the arachnoid membrane. The delicate arachnoid tissue, however, may cling to the needle and be pulled through the hole in the dura. There it impinges and forms a spout or wick for the drainage of the whole cerebrospinal fluid sac, and also prevents the rapid healing of the dural opening. In this case all the fluid secreted by the choroidal glands during seven or eight days, the time apparently necessary for the opening to close by tissue growth, will be lost by leakage into the epidural space. It is apparent, therefore, that the amount of fluid collected in the test tube will be no evidence whatever of the loss that really occurs. This was demonstrated clearly in the author's experience by a case in which he was obliged to interrupt a lumbar puncture after the membranes, in all probability, had been pierced, without collecting or seeing any fluid; nevertheless, the patient developed a typical lumbar puncture headache which lasted with severity for eight days. From these facts he concludes that it is the continuous epidural leakage of cerebrospinal fluid through a patent puncture hole that is the primary and essential causative factor of the headache. The leakage results in loss of the supporting fluid cushion at the base of the brain, which may be regarded as the secondary causative factor in the production of the headache. Pressure of the meninges by the brain weight, against the irregular bony surface of the skull, which would ensue when the patient sits up, might be considered sufficient cause for headache, but MacRobert has another explanation to offer. He believes the sudden onset of severe headache is due to the sudden heightened intracranial pressure due to rise of pressure in the cerebral veins and that its relief, when the patient lies down, is due to the fall of pressure when the weight is removed from the veins on the clivus. Then in the course of a week the puncture hole heals, the integrity of the brain cushion or water bed is re-established, and

the headache, being a purely mechanical affair, disappears. He refers to the case in which sudden death followed spinal puncture in brain tumor or other intracranial conditions, when the withdrawal of fluid deprived the base of the brain of support, and allowed such forcible descent of the pons on the clivus of the occipital bone that prolapse of the medulla through the foramen magnum occurred, and points out that the basilar plexus on the clivus of the occipital bone is formed by an extensive anastomosis of flat venous plexuses, and is connected on either side with the cavernous and inferior petrosal sinuses and with the neighboring blood channels. The other venous channels that drain the cranial cavity at the base are rigid inelastic tubes, and they are thus safe from closure by pressure. The basilar veins, on the other hand, depend on the cushion of cerebrospinal fluid to keep off the pressure of the pons, which is directly above. When the patient sits up the cushion of fluid is absent and the weight of a good part of the brain is suddenly imparted through the pons to this communicating plexus. The blood about to leave the skull is impeded and the resulting congestion causes a sudden rise of venous pressure.

Berliner klinische Wochenschrift.

February 25, 1918.

The Gastrointestinal Disturbances of War.—S. Korach has noted the great frequency of achylia and hypohydrochloria. They represent 35 per cent. of all gastric troubles as against 15 per cent. of hyperacidity. Of these affections, some were present in the patient before the war, but many subjects certainly acquired the disease during the war. While admitting the neuropathic element in play in these cases, Korach attributes these "temporary exhaustions of an insufficient mucosa" to many other causes, such as hasty eating, insufficient mastication, abuse of tobacco or coffee, dehydration from sweating, etc. In other instances emotions (fright, etc.) have produced serious disturbances of the gastric secretion, so that these more or less acute processes increase in frequency during action at the front or when units are being hastily transferred from one front to another. From the viewpoint of prognosis the acute form of achylia is far better than the chronic as a vegetable diet and salt water cure will control the former process. Korach considers that patients with gastric or duodenal ulcers are incapable of active service, even those who appear to be cured by medical treatment or gastroenterostomy, etc. From the writer's point of view some cases are needlessly operated on, and he has seen these neuropaths or psychopaths unquestionably ameliorated by the war.

The Diathermic Treatment of Gonorrhea and Other Affections.—H. E. Schmidt considers that this procedure unquestionably assures the best realization of heating the deep structures, and causes a direct hyperemia. In gonorrhea, diathermy cannot kill the gonococcus as this organism is probably more resistant when in the tissues than in cultures. One should define a just status of the question, between the enthusiasts and detractors of the method, and generally speaking, it should be combined with some more directly antibacteriologic procedure. Obstinate prostatitis is perhaps the best indication for the treatment, while in anterior urethritis quite as good results are obtained by simply heating the penis between two electrodes placed on each side of the member. Among other affections in which diathermy gives good results are muscular and joint pain, but it is less potent in sciatica and other neuralgias. It can also be employed for the removal of warts and other minor cutaneous operations.

Münchener medizinische Wochenschrift.

February 26, 1918

The Signification of Cerebral Gas Emboli in Essential Epilepsy and True Shock.—Kohlhaas, starting from Hering and Brauer's observation on pneumothorax and the ophthalmoscopic researches of Wiehand and Becker, observed the passage of gas bubbles in the arteries of the fundus oculi. The writer, therefore, concludes

that from the viewpoint of both surgery and medicine, these data are of utmost import. It is certain that air may pass from the veins into the general circulation without being retained in the lungs, even when the septum between the right and left heart is closed. From these very questionable deductions which lack anything like a sound basis, the writer desires to apply this pathological process to essential or symptomatic epilepsy and he wants his readers to believe that intestinal worms may gnaw the veins of the intestine, with the result that gas emboli arise! He says that puerperal eclampsia and traumatic shock result from the same mechanism by rupture of the abdominal veins!

Vascular Affections in Paratyphoid.—K. Sick points out the relative frequency of vascular localizations in paratyphoid fever. They more commonly arise at the end of the febrile period. They may manifest themselves by the special characters of the roseola in B. paratyphoid, when the eruption covers the body in the form of very large, disseminated spots. Such an eruption indicates a participation of the arteriolæ. The frequency of muscular cramps in the calves, as well as edema, would appear to indicate a deep phlebitis.

A Simple Means for Controlling Serious Intestinal Hemorrhage in Dysentery.—E. Maret advises the use of the following prescription:

R

Plumbi acetat, 10 grains.

Gummi arabic, 1 oz.

Alb. ovi, No. V.

Aq. dest. ad, 1000 c.c.

M. Ft. emulsio.

S. A tablespoonful every two hours.

Deutsche medizinische Wochenschrift.

February 28, 1918.

The Results of Freund's Operation for Pulmonary Emphysema.—E. Bircher refers to the happy effects that may be derived from Freund's operation, namely resection of the costal cartilages, in order to amplify thoracic expansion and to favor expansion of the lungs. Bircher reports thirty cases thus dealt with and says that in 80 per cent. the result was either a cure or an amelioration. (The cure was calculated according to the return of working capacity of the individual and the disappearance of the broncho-asthmatic phenomena) the following percentages being offered in evidence: Cures, 20 per cent.; improvement, 62.7 per cent.; stationary, 13.3 per cent.; deaths, 3.3 per cent. The ultimate outcome of the patients was likewise satisfactory. In 6 all respiratory disturbances disappeared—in one case for six years and in 2 for four years. The operation was bilateral in one case and a durable improvement resulted. Speaking of the indications, Bircher points out that surgeons tend more and more to reduce the indications first formulated by Freund. For example, Sauerburch believes that this procedure should only be employed in young subjects with a rigid chest wall and emphysema but the writer limits the operation to cases of "asbestos degeneration." The youth of the patient may render the operation useless by favoring a rapid ankylosis of the operative wound.

Five Day Fever and Neuritis of the Cauda Equina.—R. Cassirer reports a case of five day fever which was particularly long and serious, presenting at the same time the clinical picture of a neuritis of the cauda equina. Lumbar puncture gave issue to a normal fluid and Wassermann was negative both in the blood and cerebrospinal fluid. The thermic rises were regularly accompanied by a return of the pain. The writer believes that the neurotic process is similar to the tibial pain and hyperesthesias frequently encountered in five day fever. The pains may, for that matter, result from a trophic ulcerating process in the bone and the writer thought that he was able to detect a thickening of periosteum and a disfluence of the spongy structure of the tibia in his case.

Wiener medizinische Wochenschrift.

March 16, 1918.

The Pathogenesis of the Pemphigus Bulla.—F. Samberger, in his article continued from the previous

issue, states that the human skin, as in the case of some animals, possesses a respiratory function, but that generally it is in a rudimentary state. In certain circumstances (asphyxia from burying in sand, for example) this function may become active and produce an intense cutaneous congestion with formation of lymphatic exudates and pemphigus may then appear in these circumstances. The writer has observed a case of hydrorrheic dermatosis in which the hydric exudate was preceded by the sensation of shortness of breath and air thirst. The application of oxygen water to the skin had the most happy effect on the dermatosis, likewise upon the paroxysms of dyspnea. Such clinical data lead the writer to believe in the part played by cutaneous respiration.

On Trachoma.—L. Königstein remarks that this affection has extended over all Austria, but is especially frequent in Galicia and in decreasing frequency in Roumania, Istria, Dalmatia, less so in Bohemia, Moravia and Silesia. It is only contagious when secreting. The writer only met with contagion by direct contact with healthy eyes and he believes that contagion by aerial transportation is out of the question. The infectious agent is yet unknown; the intracellular formations which have been described have also been found in gonorrheal ophthalmia. These facts should draw one's attention as to a possible relationship between the two affections, a relationship which has already been implied in the old term of "chronic ocular blepharorrhea."

Le Progrès Médical.

March 9, 1918.

The Adrenalin Determination of Cardiac Resistance.—Loeper, Wagner and Dubois-Roquebert allude to the great frequency of tachycardia and cardiac erethism early in the war which led to many tests of cardiac function. While nothing new has come to light, old tests have been systematized. A source of confusion is the part played by cardiac and systemic effort, for with general failure of forces the heart too must suffer. The simple way of testing the heart is by increasing peripheral resistance, and to secure the latter one may compress the large peripheral arteries or place the subject under the influence of adrenalin. The latter drug is known to raise the blood pressure by 2 cm. of mercury through vasoconstriction. In this test it should be possible to control the heart's shadow for the presence of dilatation. The dose is 1 mgm. and the interval 1 hour, or, better, there should be a series of half-hour exposures with one hour as optimum. One hundred subjects were examined, the authors beginning with simple and passing to the more complicated cases. In the first types the cardiac areas showed no change for at least an hour, but later in a few cases the heart appeared to have undergone slight contraction. But in the true cardiac subject, with valvular lesion or hyposystolia, the shadow at once augmented, as a rule completely. Hence the two extremes were well differentiated, for the tachycardiac and erethetic heart was shown to be sound and at the other extreme far from sound. The two extremes comprised nearly all the cases, for of 50 subjects 21 showed no augmentation and 23 marked dilatation (17 of the entire heart). This leaves but 6 intermediate cases in which there was a slight contraction. The authors hold that there should therefore be no trouble in distinguishing between the two types in practice.

More Paradoxes of Smell.—An earlier article on this subject by Voivenel was noted editorially in the RECORD. In the present contribution he discusses the "odor of Don Juan," and at first the indefinable charm possessed by certain males for the opposite sex who have none of the ordinary attractions of handsome men. A case is cited of a cold woman who readily repelled the latter type but was quite powerless to resist one who had no other weapon but some obscure stupefying influence. Such characters are found in literature as well as life and naturally in both sexes. Physiology may be able to solve the enigma through the subtle power of odors. Don José thus fell a victim to Carmen. The odorous object which always gives off yet retains its power can only suggest a radioactive substance and

the power of the infinitesimal obtains in both substances. It has long ago been noted that only the virile, essentially vigorous male subject exhales a specific smell. For women the claim is made that an "odor of chastity" is recognizable. St. Phillip of Neri could judge of men as to their sexual life by their smells. In modern times it has been claimed that a sexually excited male smells like chloroform. At puberty girls begin to show great interest in artificial perfumes and often favor perfumes and flowers which have an amorous suggestion. Such activities are of course unconsciously motivated. Perhaps it is the fetid odor of the snake which hypnotizes its prey. When a woman at last "meets her master" the decision doubtless rests upon some action set up in the olfactory apparatus.

La Presse Médicale.

March 4, 1918.

The Carabelli Tubercle.—Jeanselme writes at length on this subject. When Sabouraud rediscovered this anomaly in the guise of a stigma of inherited syphilis he provoked many replies, most of which were hostile. The dentists showed that Carabelli described this anomaly in 1844 but on account of its clinical unimportance it has been ignored. It represents an arrest of development, perhaps, but is present in nearly one-half of all subjects. The discoverer called his find a supernumerary cuspid on the palatine face of the first upper permanent molar; but it differs from other supernumerary cuspids in not forming part of the grinding surface of the tooth. In 1890 Galippe, the authority on stigmata, found a similar formation in the molars of the milk teeth. The author, in the course of an independent study, has found the anomaly to be eminently familial in incidence. In some of Broca's skulls from a small Basque village thirty per cent. showed it in typical form. In this particular habitat inbreeding is common. In other Basque villages, curiously, the tubercle was rarely encountered. It may be seen in crania from all parts of the world and in neolithic and paleolithic skulls. Sabouraud was moved to include this formation among syphilitic stigmata because of its association with other dental stigmata, with clinical evidences of a non-dental character and a positive Wassermann. The author says that he has not been able to verify this, for his non-syphilitic controls showed the tubercle, as did also those of some of his colleagues, in a sufficient number. In quite a long series of undoubted heredosyphilitics the frequency was not greater.

Certain Views of Shock.—Luzoir writes upon a subject of immediate importance, for the French surgeons are skeptical about shock as an autonomous condition and would substitute shock like states of various sources. In Gwathmey's book on Anesthesia he finds a minute study of shock *per se*, which varies only with the cause. The practical view of shock as something which can in part be averted by anoci-association is conceded by French surgeons. This psychic component is naturally not the whole of shock. Peripheral irritation and the action of large doses of poisons are separate components. The less severe burns cause more shock than the deeper ones. Crile has shown that irritation of organs may raise or lower the temperature, according to the organ tested. There is a shock component in severe poisonings whether corrosive only or true systemic intoxications. Crile has shown that duration of an operation must be a shock factor and this introduces the anesthesia component. The general anesthetics are peripheral irritants as well as poisons, hence doubly disposed to aid in the production of shock. Moreover, during a long operation the subject is exposed more or less to the air and loses heat, although subnormal temperature is a symptom of shock. Gwathmey isolates anesthetic shock from surgical shock—it may readily be studied in non-traumatic cases and with a variety of anesthetics. Operative shock can hardly be studied without anesthesia, but shock under mild anesthesia is due to the incompleteness of the anesthesia, plus—in certain cases, such as laparotomies—manipulation and tugging of the viscera, this mechanical element acting as a hindrance to respiration.

Book Reviews.

NEUROSYPHILIS. Modern Systematic Diagnosis and Treatment. Presented in One Hundred and Thirty-seven Case Histories. By E. E. SOUTHWARD, M.D., Sc.D., Bullard Professor of Neuropathology, Harvard Medical School; Pathologist, Massachusetts Commission on Mental Diseases; Director, Psychopathic Department, Boston State Hospital; Vice-President, American Medico-Psychological Association, and H. C. SOLOMON, M.D., Instructor in Neuropathology and in Psychiatry, Harvard Medical School; Special Investigator in Brain Syphilis, Massachusetts Commission on Mental Diseases; Acting Chief-of-Staff, Psychopathic Department, Boston State Hospital. With an Introduction by JAMES JACKSON PUTNAM, M.D., Professor Emeritus of Diseases of the Nervous System, Harvard Medical School. By Vote of the Trustees of the Boston State Hospital, Monograph No. 2, of the Psychopathic Hospital, Boston, Mass. Price, \$5.00 net. Boston: W. M. Leonard, 1917.

ONE who dips into this volume has the sensation of passing through the wards of a well-filled hospital in the company of a clinician who is a fluent and interesting talker. The book is a harmonious medley of the brilliance of Southard with the solidity of Solomon. It is a postgraduate course in nervous syphilis. One hundred and thirty-seven patients pass in review, analyzed to the minutest detail, their symptoms explained, questions are asked and answered and the social as well as the medical aspects of these cases are clearly expounded. It is, in fact, a series of neurosyphilitic clinics analogous to the psychiatric clinic of Professor Kraepelin; each patient stands out so vividly in the mind. After going over the entire field of usual syndromes, the authors devote a hundred pages to "puzzles and errors" and thirty cases illustrating medico-legal and social aspects of the disease. The treatment is discussed very fully with its unaccountable failures and its brilliant successes. Lastly, many neurosyphilitic aspects of the present war are described. The book as a whole is not only interesting but valuable. One reads it with the absorption of a novel and turns to it for reference when an obscure case comes along. It is a text book of the future—not the dry bones of a didactic discussion, but the rich juices of clinical material.

HYSTÉRIE-PITHIATISME ET TROUBLES NERVEUX D'ORDE RÉFLEXE EN NEUROLOGIE DE GUERRE. Par J. BABINSKI et J. FROMENT. Collection Horison. Deuxième édition revue et augmentée. Price, 4 Francs. Paris: Masson et Cie., 1918.

The first edition of this work was reviewed with appreciation in the MEDICAL RECORD. This edition is said to have been exhausted in a few months. In addition to certain changes in the text, there is a special section devoted to addenda and also a formal reply to criticisms of the first edition—or rather of certain views of the author—which were made in several recent textbooks on war neurology.

AN INTRODUCTION TO THEORETICAL AND APPLIED COLLOID CHEMISTRY. "The World of Neglected Dimensions." By Dr. WOLFGANG OSTWALD, Privatdozent in the University of Leipzig. Authorized Translation from the German by Dr. MARTIN H. FISCHER, Eichberg Professor of Physiology in the University of Cincinnati. First Edition. Price, \$2.50. New York: John Wiley & Sons, Inc. London: Chapman & Hall, Ltd., 1917.

COLLOID chemistry is a topic about which we hear much at the present time. Most people, however, have but a hazy idea of what the subject means, and are repelled by the somewhat heavy and uninviting literature which abounds. The present volume consists of five lectures delivered by the author in this country and in Canada during the winter of 1913 and 1914. These lectures are thoroughly interesting and attractive, and cannot fail to appeal to every reader. It would be a good plan to read the fourth and fifth lectures first, so as to get an idea of the applications of colloid chemistry. To take only those subjects which are of immediate interest to the physician: The building up of the living tissues from the products of ab-

sorption, cell life and all the vital processes in the body, the maintenance of water in the tissues, the phenomena incident to fertilization and the early development of the embryo, the process of growth, the nature of muscular contraction, the problems of secretion, edema, inflammation, and nephritis are only some of the more important problems whose solution depends on colloidal chemistry.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia. Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price, \$6.00 per annum. December 1, 1917. Philadelphia and New York: Lea & Febiger.

THIS number of *Progressive Medicine* contains articles on: Diseases of the digestive tract and allied organs, the liver, pancreas, and peritoneum, by M. E. Reh-fuss; Diseases of the kidneys, by J. H. Austin; Genito-urinary diseases, by C. W. Bonney; Surgery of the extremities, shock, anesthesia, infections, fractures, and dislocations, and tumors, by J. C. Bloodgood, and Practical therapeutic referendums, by H. R. M. Landis. The volume is of more than ordinary interest, because the whole of the section on surgery is devoted to a discussion of Military Surgery. In some hundred and fifty pages Dr. Bloodgood gives a valuable résumé of the recent literature and work on this subject, which is not only of present interest, but which will also have marked influence on surgery in time of peace. This chapter contains a number of good illustrations, and the whole number is of permanent value.

THE EXCEPTIONAL CHILD. By MAXIMILIAN P. E. GROSZMANN, Ph.D. Educational Director of the National Association for the Study and Education of Exceptional Children. Author of "A Working System of Child Study for Schools," "The Common School and the New Education," "The Career of the Child from the Kindergarten to the High School," "Some Fundamental Verities in Education," "The Study of Individual Children," etc., etc. Containing a Medical Symposium, with contributions from a number of eminent specialists. Price, \$2.50 net. New York: Charles Scribner's Sons, 1917.

THE chief criticism of Dr. Groszmann's book is that it contains too much. The object seems to have been not to further the knowledge of a definite subject, but to present all which has been written on abnormal children and any subject even remotely connected with their examination, care and training, delinquencies, and development. The result is a conglomeration of quotations, abstracts, trite and prolix discussions of more or less apposite subjects, articles "lifted" whole from medical magazines, etc. Dr. Groszmann would have benefited himself and his school and the profession more by the concise presentation of some of the valuable experience he has undoubtedly acquired in his large experience with abnormal children.

THE CONDUCTION OF THE NERVOUS IMPULSE. By KEITH LUCAS, Sc.D., F.R.S., Fellow and Lecturer of Trinity College, Cambridge. Revised by E. D. ADRIAN, M.B., M.R.C.P., Fellow of Trinity College, Cambridge. With diagrams. Price, \$1.50. London and New York: Longmans, Green & Co., 1917.

WE approach this posthumous work with a mingling of interest and respect. It is a worth-while contribution to physiology of a man who lived for science and died for his country. Keith Lucas was killed in an aeroplane accident in October, 1916. Among his effects was the present monograph, unfinished evidently, but containing much valuable research work. The phenomena of conduction of the nervous impulse, with its problems of summation and inhibition, as demonstrated in the central nervous system, has had a host of investigators, but the peculiarities of peripheral nerve conduction have been more of a *terra incognita*. Lucas throws light on these dark places and he has had the good fortune to be edited by a sympathetic disciple whose own work is not less noteworthy. This study takes rank beside any of Sherrington.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Twelfth Annual Meeting, Held in Albany, May 21, 22 and 23, 1918.

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES.

Monday, May 20, 1918.

THE PRESIDENT, DR. ALEXANDER LAMBERT, IN THE CHAIR.

President's Address.—DR. ALEXANDER LAMBERT opened the meeting with an informal address, in which he said, in part, that when he accepted the honor of the presidency of the society he little thought that he should spend the entire period for which he had been elected so far way, but that the society could not have had in his place any better helper than Dr. Halsted. The society had lost nothing by his absence and had gained a great deal by having Dr. Halsted in his place. As he did not know what had occurred in the society during the past year, he thought they would be more interested in hearing what he had been doing in France. The questions which he had constantly been asked were: "What are your general impressions? Have you any idea how long the war is going to last? What does it really amount to?" One might answer these questions in a general way, saying that the moral effect of the war is beyond the appreciation of anyone, but the physical results had, as yet, by no means reached up to the moral effect. When the American troops first came to Paris the enthusiasm they created was unbounded. The people of Paris gathered along the sidewalks and fairly mobbed the American soldiers, hugged them, threw garlands of flowers, and broke the lines so that they were unable to reform for several blocks. That was an expression of what the people felt all over France. Dr. Lambert related an incident of one old French soldier who wanted to shake hands with him and thank him for coming over and who later brought a whole division to see him. The spirit and the morale had gone up as the months had gone along. To-day our soldiers over there were eager and anxious to fight. They had recently gotten into just a brush at Noyon. A gap was made in the French ranks and our men closed the gap and that without artillery, but simply with their bayonets. Later heavy American artillery arrived and they were still holding that point. The French were looking to us to come and help still further. Dr. Lambert said he was supervising the work of the American Red Cross, which, as they probably knew, was incorporated by Congress and controlled by representatives of the Departments of State, Treasury, War, and Navy. Its work was intended to be the volunteer care of the sick and wounded in the Army and Navy and to go wherever it was sent and to do whatever it could to help in any way. It tried, in as far as was possible, to fulfill the requirements laid down by the International Red Cross Convention of Geneva. It had succeeded to a large extent in doing this. It was also doing the work of establishing communication by mail between soldiers taken prisoner and their families. The Red Cross stood ready to help the army in any way it could, more especially on the side of amusement and recreation and hospital care. The Red Cross ceased to be Red Cross service when it was called into actual army service. As to the medical work, Commissioner Murphy showed the need for a research fund and he had obtained the co-operation of the British and French armies and a research meeting was held every month, where the medical men gave the best experience they had obtained during the three years of the war. This was a great help to our medical men, as they could go right to work with the best up-to-date 1918 surgery, instead of practicing surgery as they did before the war. Dr. Lambert said he would postpone going into medical details for the special section meetings. There was, however, one discovery worthy of record and that was that the origin and means of transmission of trench fever had been solved. Trench fever was characterized by severe

shooting pains in the muscles and regular recurrent fever. The research was carried on by a man who had worked with Leonard Wood in Cuba on the problem of yellow fever. Sixty men volunteered as subjects for experiment and in six weeks it was found that the louse was the cause of trench fever, both the ordinary louse and the trench louse. The value of this discovery would be appreciated when it was known that 10 per cent. of the English army had been on the sick list from this cause. The victims of trench fever did not die, but they were unfit for duty for from four to six months. Delousing would thus save for active service from 8 to 10 per cent. of the army. There was a drive against this research work by the anti-vivisectionists and the Christian Scientists, who took the stand that the Red Cross had no moral right to use their funds in this way. It seemed wise to the War Council to secure a special fund for research work if it were possible to do so, though at the same time not yielding the point to the anti-vivisectionists. About \$166,000 had been entrusted to him for research work and he had spent about \$30,000 when this decision was made. Through the generosity of Miss Grace Dodge he was given the \$166,000 for research work. He had come to ask aid for this work. They needed thirty, forty, or fifty doctors to assist them. The work had so occupied him that he had been unable to leave Paris to attend to other matters and his assistant was doing the work of half a dozen men. He had taken several doctors, but they had all been sent to the front and were doing excellent work and receiving the highest praise. His work, Dr. Lambert said, was plain, inglorious administrative work. The entire southern part of France would have to be redistricted. Then they had the task of breaking up epidemics of scarlet fever, mumps, and diphtheria and preventing them from getting into the camps. If men could come, but were unable to pay their own expenses, they would be given a lieutenant's salary, and if men could not come all the time, but could come for nine months of the year or even six or eight months, they would be acceptable and some one could be obtained to relieve them at the end of that time and in this way the work might be carried on continuously. One part of the service was to send out from a center a unit consisting of a doctor, a nurse, and a chauffeur, who would visit a group of villages, going to certain villages on certain days of the week. He did not want men of draft age who were needed in the army, but men who were young and vigorous, or if no longer young they must still be vigorous, as the work was hard and the climate severe. He could not take teachers from medical colleges. If such men came during the summer they would have to return in the fall to their teaching duties. In closing, Dr. Lambert said he had not done the work he had been elected to do, but this the society need not regret, as Dr. Halsted had increased both the membership and the influence of the society.

Report of the Secretary.—DR. FLOYD M. CRANDALL presented this report, in which he said that on January 21, 1907, the membership of the State society was 5,857. To-day there was an increase of 2,482. The membership of the society was increasing more rapidly than the accessions to the professions. This report also contained a letter of commendation of Dr. Halsted, who had responded to every call and performed every duty devolving on the highest officer. His duties as president of the American Laryngological Association, added to the duties of acting president of this society, had made a most laborious year, but Dr. Halsted had never been known to complain or shirk any duty.

Report of Committee on Scientific Work.—DR. THOMAS J. HARRIS of New York presented this report, which stated that in spite of the unusual conditions existing in the absence of many of the active workers of the society, which made the work of the committee somewhat difficult, it was their feeling that the program this year in every way compared favorably with those of previous years. Dr. Harris said he wished to bear witness to the wisdom of the radical change made five years ago by the inauguration of the section form of meeting.

Report of the Treasurer.—DR. FRANK VANFLEET of New York submitted this report, which showed a deficit

of \$2,877 for the year 1917. However, taking the accounts from the year 1906, some years showed deficits and some excess of income, and the excess of income during these years, as a whole, was \$5,096.

Report of Committee on Legislation.—Dr. JAMES F. ROONEY presented this report, in which he stated that the bills affecting the medical profession introduced into the Legislature during this winter were in very little wise different from those of preceding years. They might be grouped as (1) Public Health Measures, (2) Police Measures, (3) Sociological Measures, (4) Educational Measures, (5) Measures affecting the statute as to the practice of medicine. In Group 1 the only measures of general importance were two bills for the control of venereal diseases which were introduced, it is stated, as war measures at the request of the Surgeon General of the United States. One instituting a new Bureau in the Department of Health for the suppressing and curing of venereal diseases and the other for the purpose of securing the control of venereal diseases among the vagrants and prostitutes. In Group 2 was the bill introduced by the Committee of the Legislature for the investigation of the use of habit forming drugs. This act lessened very greatly the burden placed upon physicians in regard to prescriptions and distribution of drugs, but had three disadvantages—first, that of requiring an annual registration fee of all physicians; second, the institution of a separate bureau of drug control, the head of which need not be a physician or pharmacist and who was appointed by the Governor, with the consent of the Senate, for a term of six years, thus placing the whole narcotic situation practically in the field of politics; third, the bill removed from the class of privileged communications all those made by patient to physician as concerns the enforcement of the act, both as to statute and any additional regulations which might subsequently be promulgated by the commissioner. While a request was made for a hearing upon this bill before its passage, no hearing was granted by the Committee of the Senate having charge of the measure, but a hearing was granted before the Governor on April 24. Under Group 3 would fall the Senate bill introduced by Mr. Nicoll instituting a system of Compulsory Health Insurance. This bill this year purported to have been introduced at the instance of the Federation of Labor, but the same forces that had been urgent for this sort of measure were in reality the strength behind it. The most persistent of these was the American Association for Labor Legislation.

The society has been extremely fortunate in having been able under the antiquated system in use for the care of its interests in the Legislature not to have experienced serious injustice accruing to it by the passage of ill-advised and pernicious legislation for the past four years. It must, however, immediately become cognizant that this good fortune cannot recur year after year. It must realize that it has facing it three very determined forces bent upon securing their own interests regardless of the best interests of the public and of the medical profession; the sinister forces behind Compulsory Health Insurance; the activating energy of poorly informed so-called "sociologists" and "criminologists" on the question of drug addiction, and the extremely clever and highly financed forces behind which quackery was entrenched. The organization of the society was too loose; its efforts were too inordinate at present to present an effective opposition to these forces. This Committee heretofore recommended that a bureau for the study of medical legislation be established in Albany in charge of a competent person, preferably an attorney of experience in legislative affairs, for the purpose of collecting statistics and facts relating to public health and the medical profession as concerned legislation, who should be under the supervision and direct control of the society through the chairman of the Committee on Legislation. This bureau would be able to carry on the necessarily enormous work that is becoming almost impossible in magnitude for the chairman of this committee to carry during the legislative session. It would serve as a continuing and continuous administration of legislative matters; it would be a constant source of information as to the correlative work in other States and countries and this action would be well paid for in

betterment by a performance of what is coming to be one of the most essential features of organized medicine, that was a supervision over public health legislation which had thus far been too largely in the control of overzealous experts, part real and part self-constituted, whose vision had been acute at times, but not of necessity either broad or farseeing. It was further recommended that the society take some definite stand upon Compulsory Health Insurance and that it give a definite pronouncement as to its attitude on drug addiction, since it was essential that this be done to offset the villification and abuse that had been gratuitously heaped on the profession because of the defects of a very few of its unworthy members, by certain groups of persons in the community whose interests were neither unselfish nor sincere.

Report of the Committee on Medical Economics.—Dr. HENRY LYLE WINTER presented this report, which stated that the committee had studied the problem of Health Insurance, or Social Insurance, from various viewpoints. Considered as a medium for benefit to all or any of the social groups included within the scope of any plan so far advanced, it was, in their opinion, a failure. They reported, therefore, that this committee was opposed to Health Insurance. Realizing that the proponents of Health Insurance would continue their efforts to put some kind of a bill upon the statute books the committee had two tentative propositions to make. The first of these were similar to those adopted by the Medical Society of the County of New York and was as follows:

"1. The medical profession shall be properly and adequately represented on the commission, and on all committees, councils and other local boards which have to do with decisions affecting the relations of physicians with the various associations, societies, etc., working under the law, and upon all other medical matter.

"2. The commission shall prepare and publish lists of panels of physicians in all the districts who are willing to work under the act, and that every legally qualified medical practitioner shall have the right to have his name recorded on the list or panel.

"3. The sick insured person shall have the right to choose any of the panel physicians in any district to attend and treat him for his illness, subject only to the physician's acceptance of the patient.

"4. The insurance carrier shall make all contracts for medical and surgical attendance with bodies or associations of physicians in each district, to which association all panel physicians in that district must belong."

The second proposition was a tentative Health Insurance bill, which they believed would supply the worker with what he needed and enable him to pay for it, accepting from the employer only that aid for which the employer himself received full value in the better standards of health and consequently better efficiency of the employee, were, therefore, fundamentally different from prior bills and must appeal to the independent spirit and individualism of the American workman. At the same time these suggestions provided the workman with better medical treatment and increased instead of ruining the efficiency of the medical profession.

They believed that the expense to the employer incurred in their plan would prove a profitable investment by insuring a more complete return of the sick employee to health and his more prompt return to work.

Report of the Counsel.—James Taylor Lewis submitted this report, which stated that during the past year not a single case had been lost. Thirty-one cases had been finally disposed of during the year 1917. Thirty-eight new actions were brought during this year, but this did not include situations in which both husband and wife brought separate actions against the same defendant for the same case; the real number of cases brought was, therefore, in excess of this. In each year there were always one or two cases that stood out most interesting. During 1917 there were two such cases. One was a case where a patient claimed that having been sent to a hospital by her family physician and placed in the care of a surgeon, she was operated upon by him without authority from her

or her husband, for a cancer at the end of the radius, and that the operation was carelessly performed, which facts presented two very serious questions. Three different sets of attorneys appeared in this case, which was finally tried at the very end of the year; indeed, the verdict in favor of the doctor was rendered the day before Christmas. The case involved the transplantation of a piece of bone from the shin of the patient into her arm. The graft healed perfectly, but subsequently the original malady reappeared at the end nearest the hand, with a resultant serious deformity and erosion of bone. The involvement of the two serious questions—negligence and constructive assault, together with the success of the operation, even though an attack was made upon the doctor, makes this one of the remarkable cases of the year. The second case was one brought for the death of a child who was bitten by a mad dog, it was claimed. The trial of this action occupied about nine days and resulted in favor of the doctor. Briefly, the facts were that a little boy was attacked and bitten by a dog, and some six weeks later developed some of the symptoms of actual rabies. Unfortunately for the plaintiff's contention, there were other symptoms which appeared which did not coincide with the diagnosis of rabies, but did present a very plain case of poliomyelitis. A case of rabies as the foundation for an action for malpractice being so very rare, the counsel felt that he was justified in referring to this case in his report. It might be interesting to the members of the society to know that at last the Dental Society of the State of New York has awakened to the importance of organized malpractice defense. Inquiry had been made as to the willingness of the counsel of this society to defend the members of that very large and distinguished organization. After reviewing the other cases briefly, Mr. Lewis called attention to the fact that the counsel had been called upon from time to time to advise members on all sorts of subjects, and especially one of grave import, in which one of the well-known physicians of the State was attacked under the "Boylan Law" for not keeping a record of every quarter grain of morphine which he had received and dispensed. There has been an investigation in the State with reference to the sale of narcotic drugs, and there should be but one answer to the whole proposition, namely, that the Federal Enactment should be re-enacted in the State of New York just as it is, so that there will be no conflict of authority or law with reference to the purchase, sale, and administration of narcotic drugs by doctors.

Report of the Committee on Medical Research.—Dr. FREDERIC E. SONDERN submitted this report, stating that during the last session of the Legislature of the State of New York the usual measures to prevent animal experimentation were presented. The various members of the committee had given the chairman most hearty support and were also indebted to the Public Health Committee of the New York Academy of Medicine. There were no hearings on the bills and they were not reported out of committee.

Report of Committee on Prize Essay.—This committee reported that but one essay had been submitted for the Lucien Howe prize. This paper showed personal clinical observation and pathological study, and the entire article showed an intelligent and complete study of the subject. It was therefore awarded the Lucien Howe prize of \$100. The recipient of this prize was Dr. I. S. Welchsler of New York, his subject being "Ophthalmological Changes in Tabes and Paresis, Their Pathology and Their Special Relation to Cerebrospinal Syphilis, Studied in Reference to 122 Cases."

Amendments to the Constitution and By-Laws.—An amendment to the Constitution providing that all ex-presidents of the society should become life members of the House of Delegates was defeated. An amendment providing that one vice-president from each county society should become a member of the Council of the State Society was also defeated. An amendment which provided for raising the dues of members of the State Society from three to four dollars was also voted down, and a proposal to give the Council the power of taking a referendum vote of the membership of the society suffered the same fate.

These reports were accepted and the recommendations contained therein discussed separately.

Consideration of Recommendations Submitted in the Various Reports.—After a discussion of the question of establishing a legislative bureau at Albany, Dr. George W. Kosmak presented resolutions providing for the establishment of such a bureau on condition that the necessary funds were available. Dr. James F. Rooney moved that a committee of five be appointed by the president to whom all questions with reference to narcotic drug legislation be referred. Dr. Wendell C. Phillips made an amendment to this motion to the effect that inasmuch as they had a legislative committee the subject of narcotic drug legislation be referred to that committee together with the statement that it was the sense of the society that the narcotic drug law now in effect was iniquitous and should be repealed. These motions were adopted. A motion to adopt the first clause in the report of the Committee on Medical Economics was adopted, but in accordance with the wishes of the chairman of that committee the other propositions were referred back to the committee for further study. Several resolutions condemning health insurance were introduced, among them one instructing the delegates to the American Medical Association to oppose health insurance in whatever form it might be presented. A number of resolutions on the narcotic drug question were also submitted. All of these resolutions were referred to the Committee on Medical Economics.

Committee to Work for Increasing the Medical Reserve Corps.—Dr. LAMBERT stated that the American Medical Association had requested them to appoint a committee from the State Society to work in conjunction with the American Medical Association for the purpose of increasing the number of physicians in the Medical Reserve Corps. He appointed Drs. George D. Stewart, Frederic E. Sondern, Floyd M. Crandall, who were already on the State Committee of the Medical Section of the Council on National Defense. The American Medical Association had requested this action because in some States the State committees were not doing as much as they should to further the enlistment of men in the Medical Reserve Corps. The New York State Committee, however, was doing excellent work, and in order to avoid any friction that might arise from having two sets of men doing the same work, it seemed wise in this State to have the same men on both committees. Dr. Sondern would explain the work of that committee.

Dr. SONDERN stated that the New York State Committee of the Medical Section of the Council on National Defense had faithfully performed all the work asked of them by the General Medical Board. They had made an investigation of the hospital facilities of the State; they had classified the physicians of the State, and had returned a list of those who were available and desirable for service, and that was followed by a special medical census. They had conducted a recruiting campaign by having medical officers travel to every part of the State for the purpose of stimulating interest in the recruiting of medical men. They had also followed this work up afterward. They had had a part in having the present draft regulations put into effect and had secured the legislation permitting medical students to complete their medical courses and to remain in a hospital until the August following their graduation. This committee had also held general rallies and given motion picture exhibits to further enlistment, and had used its influence to start the campaign for the establishment of a volunteer medical service corps. They had supported the Owen bill, and assisted the cause for which they were working in every possible way. There was now a call for 5,000 more medical men in the army and 2,000 in the navy, and they had taken action to meet this call by sending a circular letter to all county societies and to all physicians who were classified as suitable for service. It might be of interest to know how the States were meeting the call for medical officers; Nevada headed the list, having given 26 per cent. of her medical men; Arizona came next with 23.4 per cent., then Montana with 22.5, Oregon with 21.4, Pennsylvania with 21.2; but New York with 18.6 per cent. stood tenth among the States.

Resolutions for Disease Prevention.—Dr. CHARLES G. STOCKTON of Buffalo said that the higher requirements in medical practice had reduced the number of

physicians below the actual needs before the war and the reduction would continue while the war lasted and hence it was necessary to have the highest possible conservation of physicians. Inasmuch as ignorance of the cause of disease and failure to get an early diagnosis and treatment were responsible for an increased amount of sickness he wished to present resolutions urging the cooperation of physicians in furthering a campaign for disease prevention. This would not only lessen the demands on the physician in civil practice, but that it would help our success in the war if those men at the front knew that their dependents at home were well. This would be no loss to the individual practitioner and a great gain to the world as a whole. These resolutions were adopted together with the suggestion that similar resolutions be presented before the House of Delegates of the American Medical Association and a committee of five be appointed to carry out the suggestions contained in the resolutions.

To Reduce the Size of Directory.—After considerable discussion and the consideration of a number of suggestions, a motion was carried which will reduce the size of the Directory by eliminating certain repetitions and unnecessary data which will limit its cost to from \$3,000 to \$3,500.

Election of Officers.—The following officers were elected to serve for the ensuing year: *President*, Dr. Thomas H. Halsted of Syracuse; *First Vice-President*, Dr. James F. Rooney of Albany; *Second Vice-President*, Dr. Marcus B. Heyman of Wards Island; *Third Vice-President*, Dr. William M. Dunning of the Bronx; *Secretary*, Dr. Floyd M. Crandall of New York; *Assistant Secretary*, Dr. Edward Livingston Hunt of New York; *Treasurer*, Dr. Frank VanFleet of New York; *Assistant Treasurer*, Dr. Harlow Brooks of New York; *Chairman on Committee on Scientific Work*, Dr. Parker Syms of New York; *Chairman of Committee on Public Health and Medical Education*, Dr. Joshua VanCott of Brooklyn; *Chairman of the Legislative Committee*, Dr. F. C. Conway of Albany; *Chairman of the Committee on Arrangements*, Dr. Dwight H. Murray of Syracuse; *Chairman of Committee on Medical Economics*, Dr. Henry Lyle Winter; *Chairman of Committee on Medical Research*, Dr. Frederic E. Sondern; *Delegates to the American Medical Association to Serve for Two Years*, Drs. Arthur J. Bedell of Albany, James W. Fleming of Brooklyn, Dwight H. Murray of Syracuse, George W. Kosmak of New York, and Frederic E. Sondern of New York; *Alternates*, Dr. Charles Stover of Amsterdam, J. Lewis Amster of the Bronx; G. S. Towne of Saratoga Springs, G. F. Cott of Buffalo, N. O. Brooks of Oneida.

Place of Meeting.—Syracuse was selected as the place of meeting in 1919. The date of meeting is to be decided by the council.

OPENING MEETING.

Held May 21, 1918.

THE PRESIDENT, DR. ALEXANDER LAMBERT, IN THE CHAIR.

Invocation.—Rev. R. H. BROOKS opened the One Hundred and Twelfth Annual Meeting of the State of New York with a brief prayer.

Address of Welcome.—Dr. ARTHUR BEDELL welcomed the society on behalf of the medical profession of Albany, and told of the plans arranged for the entertainment of the members of the society and their guests.

Address of Welcome.—Dr. JAMES R. WATT, Mayor of Albany, made a brief address of welcome on behalf of the city, in which he said he had been shown a copy of the by-laws of the society by one of the officers of the society and his attention was called to the ruling that no speaker was permitted to hold the floor for more than twenty minutes. He could not say whether this was done for his own benefit or for that of the audience, but he would not trespass on their time except to bid them welcome again to Albany. The society had been born in Albany and spent its youth and early maturity here and Albany welcomes them home again with a parental interest and a pride in their achievement.

Patriotic Address.—Mr. HERZOG of Albany, in the absence of the Governor, made a brief address. He said he had been asked to make an address on Thrift

Stamps, but that was one of the ways a man could "do his bit," or, rather, his best. He said that America wanted no peace until this war preparation was settled right and once for all. They wanted no peace until there should be no more violation of treaties. They wanted no peace until there should be no more murders such as they had witnessed in the sinking of the *Lusitania*. They wanted no peace until they could be assured that their women and children would not be treated as those of the Belgians and French had been treated. Mr. Herzog stated that he was of German descent, but that there was no one in America more patriotic than he and he wanted to bring home to the people the fact that they were not fighting simply the Kaiser, as was so often said, but they were fighting the whole German people. They had a public school in the south of Albany which was considered the best school in the city and 98 per cent. of the children were German. The reason they gave no trouble was because obedience was inbred in those children and the same was true of the German people. They were ruled by fear and were absolutely under the domination of the Kaiser. It was not the man who was of German descent and who had become Americanized that we had to fear, but the so-called American next door who said he was neutral. There was today no place in this country for the man who was neutral. Furthermore, the man who said anything that was not absolutely loyal to France, England, and Italy was throwing bullets at our own boys who were fighting for us. Some people said they could not afford to buy stamps or bonds. They were not yet awake. We did not know as yet what it meant to make sacrifices. We had still to learn the beauty and necessity of making great sacrifices.

Oration: The Psychology of the War.—Hon. JAMES M. BECK, LL.D., of New York City delivered a most eloquent oration which he prefaced by stating that under the present stress and strain incident to the war he could not sit down in cold blood and write an ornate oration or an academic essay, but that if his address were neither of these it at least had the merit of sincerity. It had occurred to him that perhaps a body of this kind would expect something more from him than merely a patriotic address, so he had decided to discuss the psychology of the war, not the psychology of the art of war but the psychology of the nations engaged in this war. He was persuaded that they would never understand the causes of this war until they understood the psychology of the nations participating in it, and what was more they would never understand the problems involved in reconstruction until they understood the psychology of these nations. To enter into the psychology of each of these nations would be a task too great for the time allotted to him, so he would resort to the art of analogy. The art of analogy occupied to literature the same relation as the motion picture did to the drama; it gave a maximum of impression with a minimum of effort. It gave an abstract truth in a visual form. Analogy had been employed by the master psychologist of all time, though he was not a professor of psychology and had never written learned books like a Munsterberg, but was one who knew how to depict all the great emotions of the human soul. There never was such a master of analogy as Shakespeare. He was such a master of his art that physicians thought he must have been a physician and lawyers thought he must have been a lawyer, but after all he had drawn most of his analogies from his own craft. The speaker said he had found in Shakespeare's plays 420 allusions to the theater. A number of these he quoted: "All the world's a stage and men and women merely actors." "This wide and universal theater of man presents more woeful pageants than are seen in the theater wherein we play." etc. Of all his analogies those drawn from history were most notable, yet he never put upon the stage such a stupendous tragedy of history as that which was now being enacted. This great drama now being enacted was one which had been drawn by this great protraiter of character in his play of Hamlet. Mr. Beck then proceeded to outline the plot of the play and draw his analogy with the present war situation. If one took the nations to-day and the characters of Hamlet the analogy was per-

fect. Prussia was the usurping king of Denmark, who, in the summer of 1914, found the whole world sleeping. There was never a brighter outlook for the fraternity of the nations than at that time; there was not the least cause for international friction. It was then that Prussia poured into the ear of the sleeping nations the cursed henbane which has cost the world the loss of at least ten million men, women and children. It must be observed that Shakspeare did not make the brother of the king of Denmark altogether bad. Of all Shakspeare's characters, Iago was the only one unreservedly bad. Claudius still has a consciousness that Heaven was not deluded when he said "My words go up, my thoughts remain below, and words without thoughts never to Heaven go." Prussia had to-day a gnawing remorse at its soul as was shown by the words of the Kaiser on three occasions "God knows I did not will it," though he knows well that God knows he did will it. But this was as nothing compared with the verdict the world had brought. It had put the brand of Cain on the brow of the German people and in virtue of this verdict the cause of the Allies had already triumphed for it had rendered an irrevocable verdict against Germany and even if Germany should triumph in arms she would be in the position of the murderer who had his victim strapped to his back and cried out: "Who shall save me from the body of this death." This was the burden which Germany must henceforth carry. Gertrude in the play was Germany in distinction from Prussia. Prussia was the royal family of Germany, the diplomats, the professors, capitalists, those in high places. Germany was the great people, chemists, biologists, laboring people, small traders, etc. While nothing was said except behind closed doors there was a distinct line of cleavage between these two classes, not only as to the policy of the war but even as to its righteousness. It was vital that we should make this distinction between Prussia and the German and the people. In dealing with Germany, however, we must go further than merely the Potsdam gang, we must say to Germany, as well as to Prussia, so long as you sit at the bar of the world cynical and unashamed and unrepentant, just so long we will not buy from you, we will not sell to you, and we will drive you from among the nations as Cain was driven from the gates of Paradise. But it must be remembered that Germany was not entirely hopeless so long as there remained such men as Carl Liebknecht.

To come back to our play, Laertes in the play was Austria. Laertes was the passionate, impulsive man who never stopped to think. Those were the qualities in Austria that were leading her to her doom. To bring out the analogy, the speaker related the events that precipitated Austria into the war and pictured Austria perishing in consequence of her impulsiveness just as Laertes perished by his own poisoned foil. Austria was gone forever, chained to the chariot of Prussian power. In the last part of the play Laertes stood craving forgiveness and Hamlet said to him "Heaven make thee free, but as for me I can never forgive." Rosencrantz and Guildenstern were, of course, Bulgaria and Turkey, and Polonius, with his graphophone type of intellect and lacking the creative impulse, was Russia, and Polonius was one of the greatest tragedies the world had ever known. Joffre had told the speaker, in 1916, that he knew the war would be over in a year because he knew the forces and equipment on the western front were more than Germany could withstand at that time, when she was also engaged on her eastern front with Russia. There crept into the stereotyped Russian mind such maxims as "Peace without victory," "Peace without annexation," "Freedom for all," etc. Russia had been traduced by socialism of the Bolsheviki type. Shakspeare could hold the mirror up to nature in even his minor characters in a most extraordinary manner.

We had in Horatio, the steadfast, loyal boy, with his clarity of vision and his nobleness of character, the prototype of France. What an apology the Anglo-Saxon race owed to France. She had been judged frivolous, bright, inconstant, exuberant like her own champagne. In these years of war her women and

children had cared for her vineyards. Let those remember who in years to come drank the champagne of the vintage of 1914 to 1918 that he was drinking what was made at the cost of the sweat and the tears of the women and the children of France. With a quiet, steady determination and without asking help from anyone France had lost 250,000 men and still stood steadfast against the mighty army of the invader. Words failed to picture this wonderful people so ennobled and glorified by sacrifice. Ophelia was, of course, Belgium with the one difference that Ophelia was weak and there was no one who would attribute weakness to Belgium. Belgium had held back the Germans as the Greeks held back the Persians at Thermopylae.

Fortingras, the Norwegian viking, comes in at the end and "makes mouths at invisible events." Fortingras was England. She saw no reason for entering a quarrel the issue of which was not clearly defined. She did not know whether India might not rebel, or South Africa, or Australia, or Canada, but when the appeal finally came she no longer hesitated. She entered the war on August 4, 1914, and by August 8 she had 100,000 men crossing the channel. England found quarrel in a straw when her honor was at stake and she had plighted her honor to Belgium.

Thus far, Mr. Beck said, he had depicted a play of Hamlet without Hamlet. Who was Hamlet? In his judgment Hamlet was our country, and in saying this he was not uncomplimentary to our country. Hamlet was one of Shakspeare's greatest characters and his favorite child. He was the scholar, the courtier, the soldier, but he had one fundamental fault, and that fundamental defect America possessed. It was hard to tell what the character of this country might be in the future but there was one fundamental fault in this country during the period which preceded our entry into the war. It must be remembered that every nation had a dual personality. It had the personality that was the aggregate of its living citizenship, and that which it inherited from its institutional history. America, in its personality of a living citizenship, was composed of one hundred million human beings, as Roosevelt expressed it a "polyglot boarding house." In its historical personality America was the result of its history from the landing of the Pilgrim fathers, through the war of the Revolution, the War of 1812, and on through the Civil War. In its personality of a living citizen, America was swollen with material prosperity. The lesson of history was that material prosperity and luxury were the cause of national decay. We came out of the Civil War a strong and vigorous people, chastened by sacrifice, but of later years we had become surfeited with material things, just as Hamlet came from Wittenburg "fat and scarce of breath," like every pampered son of luxury, his excessive physical life had sapped his mental power and will. That was the position we found ourselves in at the beginning of the war. In our traditions and outlook we were provincial so far as world politics was concerned. Until recently America's interest in the war was purely academic. History would regard with horror her attitude during the early years of the war. Our fault was that of Hamlet, we had developed the contemplative faculty to excess. He lacked the nice balance between inward and outward things. Just as the man who lived a gross material life was likely to act without restraint and act impulsively, so the man of prodigious mental activity might lose the power to act. He found "his resolution sicklied o'er with the pale cast of thought." Our detached attitude with reference to the war was the result of our historical experience. We had been the shuttlecock of European politics and this had led Washington to initiate a policy of detachment to which we had adhered. If we had met the crisis that confronted us at the time of the sinking of the Lusitania it was not too much to say that the cause of the Allies would have triumphed, and that the history of Russia would be very different. Our failure to be prepared and to meet the crisis in 1914 was not alone the fault of the Government, it was due to a psychological defect in national character, to excessive development of the introspective faculty, to having centered our observa-

tion on internal affairs until it was almost too late. Hamlet perished because of his dilatoriness; it was to be hoped that the analogy would not be carried to the end in our case, but that we would awaken ourselves to vigorous action and save our national life.

SECTION ON PEDIATRICS.

First Day—Tuesday, May 21.

DR. T. WOOD CLARKE OF UTICA IN THE CHAIR.

The Diarrheal Diseases of Infancy.—ROBERT SLOAN of Utica presented this paper, in which he discussed certain points in regard to the various diarrheal diseases of infancy which he had found of particular interest in private practice. Infants fed on the breast were not as subject to diarrheal attacks as were those artificially fed, neither was the diarrhea as fatal. When the mother was under the impression that she had insufficient milk for her child, it was the writer's custom to weigh the baby before and after feeding. This simple procedure showed the mother the amount of milk the infant received. If the infant was losing weight the mother's milk was analyzed. If this was found deficient artificial feeding might be substituted and the breast discarded entirely. Frequently the baby was put on artificial food, very badly managed in reference to all of its habits, and the physician was not called to see it until a severe diarrhea had developed. Usually after a thorough rearrangement of the child's, or better, the parent's habits, the child would make a speedy recovery. In a number of instances an infant would be able to take food of a most faulty character, inducing indigestion, colic, an malnutrition, yet in the cooler weather one met with no diarrhea or a diarrhea of a temporary and easily controlled form. Pure milk properly modified was undoubtedly the best artificial food for infants.

In February of 1917 there was an outbreak of diarrhea in the city of Utica which was very puzzling. Investigation of the cases showed that the majority of them took milk from the same farm, a milk which up to this time gave a count of 1 to 3,000 per cubic centimeter. A count taken at the time of the outbreak was from 300,000 to 1,000,000 per cubic centimeter. It was found that the hose used in connection with the milking machines had become contaminated. It was impossible to thoroughly sterilize the hose, no matter how carefully it was washed. Due to mechanical trouble in the milking machines, they suddenly stopped using them and the epidemic of diarrhea suddenly ceased. Other mistakes in diet and hygiene that predisposed to diarrhea were allowing a child to have all the candy it desired. The writer believed that sugar in the form of candy should be prohibited until after the fifth year. A great many infants were dressed too warmly. In the summer months all that was necessary for the infant to wear was a light flannel or linen garment. An infant should never be allowed to perspire, as it sapped the vitality and irritated the child. There was another form of diarrhea to be considered and that was the diarrhea of starvation. During the past two years the writer had had a number of these cases come under his observation and in only one instance was the baby breast fed. These children were the picture of starvation; they seemed to want their food, but were too weak to nurse. The respiration was very rapid, the pulse lost except with the stethoscope, the abdomen distended and tympanitic, the bowels very loose. The stool was liquid and of a light green color. It was this class of cases that had given him the most difficulty, and which most often proved fatal. Prophylactic treatment was, of course, best. The mothers should be educated in the proper care of the infant and it was essential to keep the infant under the closest supervision, so as to recognize and treat any digestive disturbance early. The infant during an attack of diarrhea in the summer should be kept out of doors, and restlessness allayed by a tub bath, starting at a temperature of 100° F. and gradually reducing it to 85° F. The writer has seen no benefit from taking the child to the seashore or other summer resort. The medicinal treatment was then usually advocated. In the starvation diarrhea no cathartic was administered, as the intestinal tract had been cleansed and the

infant could not stand it. The medication in this type of cases consisted of bismuth subnitrate, 10 grains for an infant one month old. The dietetic treatment which had given the best results was the feeding of undiluted whole milk, regardless of age, giving it at first with a medicine dropper. The writer cited several cases of infantile diarrhea of the starvation type.

Intestinal Intoxication in Infants.—DR. OSCAR M. SCHLOSS of New York presented this paper, in which he stated that infants suffering from a severe type of diarrhea, presenting symptoms of somnolence, coma or stupor, convulsions, and great prostration, to which the term "intestinal intoxication" had been applied, presented some important abnormalities. The blood was often more concentrated than normal, both in relation to the plasma, the corpuscles, and the amount of dissolved solids. There was a retention of nitrogenous waste products similar to that occurring in uremia. Such blood changes demonstrated the presence of diminished kidney function. This was not due to an anatomical kidney lesion, but to the depleted water supply of the body and the diminished blood volume. All the available evidence seemed to point to the fact that the acidosis met with in these cases was due to defective kidney function. There were three important considerations in the management of these cases. The fluid of the tissues must be replaced, the secretion of the urine must be reestablished, and the acidosis must be eliminated. The treatment directed toward the first and second of these conditions was identical and consisted in the administration of large quantities of normal saline or Ringer's solution. The amount should be sufficient to reduce the blood concentration to normal and to keep up a normal secretion of urine. A fairly accurate guide to the administration of fluid was the estimation of the hemoglobin by the method of Haldane. If the blood was more concentrated than normal the hemoglobin was increased and fluid should be given in such cases until the hemoglobin was normal. In most of the severe cases of intestinal intoxication it was necessary to give fluid intravenously, intraperitoneally, or subcutaneously. The intravenous method was not desirable except for one or two injections. Intraperitoneal injection of saline was a very satisfactory method, and in the writer's opinion was the method of choice. With the use of perfectly obvious precautions it was without danger. Fluid should be given until the blood concentration was normal and there was a normal secretion of urine. A valuable adjunct in promoting the secretion of urine was the intravenous injection of dextrose. This should be given in 15 to 20 per cent. solution, and from 3 to 5 c.c. per kilo body weight was sufficient. It should be given merely as an efficacious diuretic. Giving the intravenous injection through the longitudinal sinus was the method of choice. On Dr. LaFetra's service at Bellevue they were using a 20 to 21 gauge needle only ½ inch in length, with a short beveled point. With this needle transfixion of the sinus was practically impossible. All the injection should be given by gravity; the upper level of the fluid column should not be more than 1½ feet above the head of the patient. The acidosis which occurred in intestinal intoxication required special treatment based on the determination of the carbon dioxide tension of the alveolar air. In every instance the amount of sodium bicarbonate required should be determined from the carbon dioxide tension of the alveolar air or from the plasma bicarbonate. When the latter was determined the formula of Palmer and Van Slyke might be used to estimate the amount of sodium bicarbonate to be given. If these tests could not be made, all cases of intestinal intoxication should be given sufficient sodium bicarbonate to change the reaction of the urine to normal. Litmus was not a good indicator for this purpose, but the reagent of Neubauer was satisfactory. If the patient was not vomiting and the diarrhea was not severe, sodium bicarbonate might be given by the mouth in 3 to 5 per cent. solution. There might be some danger in giving too large doses of sodium bicarbonate, a danger sufficient to make it desirable to gauge the dose accurately. During the first twenty-four hours, until the water loss was replaced, the acidosis eliminated, and the secretion of urine reestablished, the diet should consist of cereal decoctions only. For the subsequent feeding there was nothing new to offer.

The Use of Dry Milk in Infant Feeding.—Dr. ROGER H. DENNETT of New York read this paper. Dry milk had been known abroad for many years; it was prepared by evaporation of fresh cow's milk. The resulting powder was preserved in cans and prepared for use by dilution in hot water. Numerous observers had obtained good results in infant feeding with the use of dried milk, especially in dyspeptic cases. The advantage of this food, which contained nothing but the pure milk substances, over proprietary foods of various kinds, was obvious. If such additions as sugar, starch, flour, etc., were needed, they could be added. It would seem as if dried milk was especially adapted to infants who had received some food injury and was more easily assimilated by them than raw milk or boiled milk mixtures. A close study of fifty cases in private practice had led the writer to the conclusion that dried milk possessed a great superiority over raw or boiled milk and that cases where the infant did not prosper on ordinary milk mixtures could be much improved by feeding with dried milk. The improvement was often marked and instantaneous. In cases where there was no constitutional disturbance, such as tuberculosis, syphilis, etc., the results were surprisingly good, vomiting having been easily controlled and increase in weight having followed at once. A weight chart was shown, illustrating the weight curve of the normal infant, compared with the weight curve (average) of fifty cases studied. When the dried milk was begun they averaged $3\frac{1}{2}$ pounds below the normal. By the time the food was discontinued they averaged normal weight. In commencing treatment with the dried milk, it was necessary to give less than the actual needs of the infant at first and gradually increase the tolerance to the food. This was a much quicker process with the dried milk than with raw cow's milk. No cases of scurvy or rickets occurred in this series, but all babies received orange juice as a routine supplementary measure. Cases with malnutrition recovered with unusual promptness under this regime. The lessening of bulk, the ease of sterilization, and the digestibility of dried milk were, Dr. Dennett said, very distinct advantages in the use of this preparation.

Report of a Case of Pica, with Unique Complications.—Dr. ARTHUR W. BENSON of Troy, N. Y., made this communication. The subject, he said, was of considerable interest, but the literature contained very few references. A report of a case was therefore presented. The patient, a girl of 7 years, returned from school on November 15 last, feeling ill and complaining of severe headache. Late in the afternoon she vomited the entire stomach contents. This was followed by a normal bowel movement, and a little later she passed what appeared to be a raw apple and tomato. There was severe abdominal pain and retching. From Thursday night to Saturday the bowels moved repeatedly. The movements were bright red blood and mucus and were accompanied with severe colicky pain. She also frequently vomited green material. No nourishment was retained and there was great prostration and exhaustion. On Sunday night, while on the bed-pan, a metallic noise was heard, and the child passed a piece of lead, 1.8 cm. long by 1.3 cm. wide and 0.4 cm. thick. This was grooved lengthways and a cuboidal prominence projected from the roughened surface. The sharp edges seemed to be mechanically responsible for the bleeding. It was discovered that this piece of lead was part of an ordinary kitchen knife, which was known to have been missing for at least two years. How it traveled through the gastrointestinal tract was not known. Shortly after the passage nausea and vomiting ceased and the child was ravenously hungry. The last bloody stool was passed eight hours after the expulsion of the foreign body. The movements decreased in frequency but continued to be streaked with tarry portions. As the bowels continued to move four or five times a day she was taken to the hospital and kept on meat-free diet with medication of calcium lactate 15 grs. t.i.d. A warm starch enema was given every morning. Patient was last seen on March 12 in good health with hemoglobin of 94 per cent. The past history of the child was instructive. She was a full term child, normally healthy, and there was no history of syphilis or of nervous or mental disease

among her antecedents. She was nursed for a few weeks only and then weaned suddenly and put upon uncertain mixtures of sugar, water and milk. She early developed an abnormal appetite, never satisfied, and a craving for highly seasoned food. From babyhood she was observed to swallow dirt, pebbles, fruit, stones, soap, etc. She devoured pencils and rubber ends with relish. Her intellect was precocious and she could memorize with startling facility. In disposition she was lazy, greedy, selfish, ungrateful, vindictive, and unreliable. She frequently bit and kicked her playmates. She evinced a shocking knowledge of sexual subjects, although her home surroundings were irreproachable. Such cases of perversion of appetite fell into three classes: (1) allotriophagia or desire for disgusting substances; (2) malacia or craving for highly spiced foods; (3) pica or eating of dirt, wood, soap, etc. The latter had been noted among animals, was common among the insane and among hysterical persons. In children it began at an early age, and was accompanied with marked deterioration of general health. Rickets, anemia, tuberculosis, might be predisposing causes. Observers had noted its association with nervous and digestive disorders. Holt had placed it among injurious habits of infancy such as masturbation, nail biting and head banging. Thomson, in outlining treatment, did not advise the use of medicines. He advocated: (1) withholding of substances for which a morbid craving was evinced; (2) rectification of digestive disturbance; (3) improvement of general health; (4) change of environment, and also keeping the children both busy and happy.

Complement Fixation Test with a Specific Antigen in Acute Poliomyelitis.—Dr. MARCUS NEUSTAEDTER of New York read this paper, in which he reviewed the difficulties of making a diagnosis when one was dealing with a polioencephalitis. The medical profession had felt all along that some additional test was necessary to point at least with some amount of certainty to the correctness of the diagnosis in this type of poliomyelitis. Having succeeded, in collaboration with Dr. E. J. Banzhaf at the Research Laboratories of the Department of Health in New York City, in producing an antipoliomyelitis horse serum by injecting two horses with the virus of poliomyelitis previously digested with trypsin, it occurred to them that they might possess in it an antigen potent enough to produce a complement fixation in sera and spinal fluids of typical and suspected cases of poliomyelitis. Such a specific antigen they had obtained by the method described in this paper. They had examined 152 spinal fluids and 60 blood serums of poliomyelitis cases, the cases being frank and suspected, in the febrile and afebrile stages. The duration of the disease was from one to forty days. The results of the tests showed that of 42 of the spinal fluids of frank and suspected cases of poliomyelitis 23, or 53.5 per cent., gave a positive reaction, and 12, or 27.9 per cent., a doubtful one, while 4, or 9.5 per cent., gave a negative reaction. Spinal fluids from cases of tuberculous meningitis, epidemic cerebrospinal meningitis, tertiary syphilis, and of other diverse pathological conditions were tested as well as normal spinal fluids, and only one gave a strongly positive reaction with the poliomyelitis antigen; seven were anticomplementary, and the rest were negative. Of 60 blood serums of various pathological conditions, none gave a positive reaction with the poliomyelitis antigen. In conclusion it might be said that an antigen had been found which probably was a specific and fixed complement, and hence was of positive diagnostic value in poliomyelitis. The result was in accord, Dr. Neustaedter said, with the production of immune bodies in a horse injected with the poliomyelitis virus digested with trypsin as described.

(To be continued.)

Cerebrospinal Meningitis Posing as Malaria.—Serr and Brette saw an intermittent type of fever in an abortive type of meningitis. The attack followed a lymphangitis of the foot. Only when stiff neck appeared was lumbar puncture practised with positive finds. Intraspinal antimeningitis serotherapy, by promptly curing the case, corroborated the diagnosis.—*La Presse Médicale.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEW YORK STATE BOARD OF MEDICAL EXAMINERS.

January, 1918.

ANATOMY.

1. Describe the thorax and name the bones entering into its formation.
2. Name the muscles of the gluteal region and give the origin, insertion, nerve supply, and action of one of them.
3. Describe the veins from the termination of the right internal jugular vein to the heart and mention all the vessels that empty into them.
4. Give the origin, course and relationship of (a) the internal mammary artery (*arteria mammaria interna*), (b) the deep epigastric artery (*arteria epigastrica inferior*). Describe their anastomosis.
5. Describe the ventral division of an upper thoracic nerve (*nervi intercostales*).
6. Give the microscopic appearance of nerve fiber.
7. Describe the crystalline lens (*lens crystallina*).
8. Describe the umbilical cord (*funiculus umbilicalis*) and name its constituent parts.
9. Give the location of the epigastric region and mention the viscera contained therein.
10. Describe the cervical portion of the gangliated cord of the sympathetic nerve (*pars cervicalis systematis sympathici*).
11. Describe the pituitary body.
12. Describe the semilunar valves, the tricuspid valve, the ileocecal valve, the valve of Vieussens and the epiglottis.

PHYSIOLOGY.

1. Is a muscle dependent on its nerve connection for the reception of a stimulus? Explain.
2. Describe (a) fetal circulation, (b) fetal respiration, (c) fetal digestion.
3. What is the function of (a) the cerebrum, (b) the optic thalamus, (c) the cerebellum?
4. What is the function of the calcium salts in the body? What food substance supplies the largest percentage of calcium salts at the time of life when they are most needed?
5. Describe the physiological process of the absorption of carbohydrates, fats and proteins in the small intestines.
6. Describe in detail the coagulation of the blood.
7. Describe the perversions of function that may cause icterus.
8. What controls the secretions of the stomach? How is this proved?
9. What is the respiratory quotient?
10. What are the avenues for the discharge of water from the system? Give the percentage of water discharged from each.
11. Discuss the physiology of equilibrium.
12. How is the cornea nourished?

ANSWERS.

ANATOMY.

1. The *thorax* is a bony-cartilaginous cage, which is bounded behind by the twelve dorsal vertebrae and the posterior part of the ribs; in front by the sternum and costal cartilages; on the sides by the ribs and intercostal spaces with the intercostal muscles. It is conical in shape, being broadest below. It contains the chief organs of respiration and circulation. The superior aperture transmits the sternohyoid and sternothyroid muscles, trachea, esophagus, thoracic duct, inferior thyroid veins, longus colli; innominate, left common carotid, left subclavian, internal mammary, and superior intercostal arteries; right and left innominate veins; vagus, phrenic, cardiac, sympathetic, and left recurrent laryngeal nerves; the apex of each lung also projects through the superior opening. Below is the subcostal angle. Its lower boundary is the diaphragm. The bones entering into its formation are: The twelve dorsal vertebrae, the sternum, and twenty-four ribs (twelve on each side).

2. The *muscles of the gluteal region* are: Gluteus maximus, gluteus medius, gluteus minimus, pyriformis, gemellus superior, gemellus inferior, obturator internus, obturator externus, and quadratus femoris.

OBTURATOR EXTERNUS. *Origin:* Body and ramus of os pubis, ramus of ischium, and obturator membrane. *Insertion:* Digital fossa of femur. *Action:* External rotator of thigh. *Nerve supply:* Obturator nerve.

3. The *right internal jugular vein* terminates (with the right subclavian vein) to form the right innominate vein; this latter is about an inch in length and passes from behind the inner end of the clavicle, downwards and inwards to the lower border of the first right costal cartilage, close to the sternum, where it unites with the left innominate vein to form the superior vena cava. This latter vessel is about three inches long, and descends almost vertically to the level of the upper border of the third right costal cartilage, where it enters the upper and back part of the right auricle of the heart. About the middle of its course it pierces the pericardium. The *tributaries of the right innominate vein* are: The vertebral, inferior thyroid, internal mammary, and first intercostal vein of the same side; the *tributaries of the superior vena cava* are: Right azygos vein, and pericardial and mediastinal veins.

4. The *internal mammary artery* arises from the first part of the subclavian artery and passes downwards, forwards and inwards, behind the inner part of the clavicle and the first costal cartilage. It then descends vertically behind the costal cartilages as far down as the sixth intercostal space where it divides into the musculophrenic and superior epigastric arteries. It lies about half an inch from the margin of the sternum. In front of it are the pectoralis major, and the upper six intercostal cartilages, intercostal muscles and intercostal nerves. Behind it are the pleura (above) and the triangularis sterni (below). Laterally are the two venae comites. The superior epigastric artery passes downwards, through the diaphragm, enters the sheath of the rectus abdominis lying at first behind this muscle and then entering it. In this muscle it anastomoses with the deep epigastric artery. The *deep epigastric artery* arises from the external iliac artery, about 1 1/4 inch above Poupart's ligament. At first it passes between Poupart's ligament and the lower border of the internal abdominal ring. It then passes beneath the rectus abdominis muscle and enters the sheath of this muscle over the semilunar fold of Douglas, passing vertically upwards between the muscle and its sheath; it then enters the muscle and about two inches above the umbilicus it ends in branches which anastomose with the superior epigastric branch of the internal mammary artery. The deep epigastric lies at first between the peritoneum and the transversalis fascia and is crossed by the vas deferens near the internal abdominal ring.

5. The *ventral divisions of the upper thoracic (intercostal) nerves* enter the intercostal spaces behind, and pass forwards with the intercostal vessels and lie below them. They are situated between the posterior intercostal aponeurosis and the pleura. At about the level of the angle of the rib they lie between the intercostal muscles and are sheltered by the subcostal groove of the superior rib. They are here below the vein and artery, and pass forwards till they reach the middle of the ribs, when they enter the substance of the internal intercostal muscles. At the anterior extremities of the ribs the nerves emerge from the muscle and pass inwards, lying first upon the parietal pleura and then upon the triangularis sterni, crossing the internal mammary vessels. When near the sternum they pierce the internal intercostal muscles, anterior intercostal aponeurosis, pectoralis major, deep fascia and skin, supplying the skin of the chest wall and mammary gland.

6. **NERVE FIBERS.**—"Medullated nerve fibers usually consist of three parts: (a) axis cylinder, (b) medullary sheath, (c) neurilemma. An *axis cylinder* is a cell process that carries an impulse away from the nerve cell. It is a slender cytoplasmic process and may be very long, as is the case with the motor fibers that come from nerve cells in the anterior horn of the spinal cord and extend, without interruption, to muscles in the distal parts of the limbs. The axis cylinder presents a

longitudinal striation, a fibrillar structure, that is supposed to be continuous with the cytoplasmic striation of the cell body. The fibrils are imbedded in a fluid protoplasmic substance, the neuroplasm, and the whole surrounded by a delicate membrane, the exolemma. Implantation cone is an elevation that is sometimes present at the junction of the axis cylinder and cell body. The *medullary sheath* (white sheath of Schwann) is a covering to the axis cylinder. This sheath never extends to the nerve cell, but begins a little distance from it. Nodes of Ranvier are constrictions of this sheath at regular intervals. The smaller the fiber the greater the distance between these nodes. Long fibers are slender, with long distances between the nodes; short fibers are coarse, with short distance between nodes. The *neurilemma* is a thin, structureless membrane that surrounds the medullary sheath. An oval nucleus is present in this sheath, midway between the nodes of Ranvier. At each node the neurilemma is constricted and touches the axis cylinder, which in turn may be slightly thickened at this point and may give off a collateral. Medullated nerve fibers with a neurilemma are found in the cranial and spinal nerves. Medullated fibers without a neurilemma are found in the brain and spinal cord. The neurilemma gives great strength to the fibers. Its absence in the brain and cord accounts for the pulpy soft nature of this tissue." —(Hill's *Histology*.)

7. "The *crystalline lens* consists of a biconvex transparent body inclosed in an equally transparent homogeneous capsule. It varies from eight to ten mm. in diameter, and is from three to four mm. thick from pole to pole. Its posterior surface rests against the vitreous, and its anterior surface against the posterior surface of the iris. The capsule is thickest at the anterior pole. The lens is enveloped at its periphery by the suspensory ligament and behind by the hyaloid membrane. The substance of the lens is arranged in concentric layers, composed of minute fibrils somewhat hexagonal on horizontal section, which dove-tail into one another. The external layers are soft, the next firmer, and the central form a hardened nucleus. Between the layers and among the fibers is an oil-like material called the *liquor Morgagni*, which permits change of form of the lens without friction. The anterior capsule is a tough, elastic membrane, lined on its posterior surface by hexagonal cells whose function, it is said, is to nourish the lens proper. The *zone of Zinn* is the *suspensory ligament of the lens*, and serves to retain the lens in place. It is a transparent, fibrous, perforated membrane, stretched between the ciliary processes and the lens. Between the folds of this ligament is the *canal of Petit*, encircling the equator and containing a fluid supposed to assist the nutrition of the lens." (Gould's *Compend on Diseases of the Eye*.)

8. The *umbilical cord* connects the fetus with the placenta. At the end of pregnancy its average length is about 22 inches, but it may vary very much either in excess or defect. It presents a spiral appearance, chiefly due to the winding of the two umbilical arteries around the umbilical vein. Its constituent parts are: Two umbilical arteries; umbilical vein; remnants of yolk sac, allantoic stalk, and vitalline duct; Wharton's jelly; and a covering, derived from the ectoderun.

9. The *epigastric region* is the middle region of the upper zone (of the nine regions into which the abdomen is arbitrarily divided). Its contents depend on the location of the lines (which differ in nearly every textbook). When the superior horizontal line is drawn between the cartilaginous ends of the tenth ribs and the vertical lines upward from the iliopectineal eminences, at right angles to the upper horizontal line, then the epigastric region contains the liver, stomach, gall-bladder, duodenum, and pancreas.

10. The *superior cervical ganglion of the sympathetic nerve* is a fusiform enlargement of the sympathetic nerve, about an inch in length, lying behind the internal carotid artery, and upon the rectus capitis anticus major opposite the 2nd and 3rd cervical vertebrae. It gives branches of *communication* to the 9th, 10th, and 11th cranial nerves, to the four upper cervical nerves, and to the middle cervical ganglion; and branches of *distribution* (1) to the internal carotid artery, forming the carotid and cavernous plexuses; (2) to the branches of the external carotid artery;

(3) to the pharyngeal plexus; (4) laryngeal filaments which join the superior laryngeal artery; and (5) the *superior cardiac nerve* to the cardiac plexus.

The *middle cervical ganglion* is of small size, and is connected with the 5th and 6th spinal nerves. It lies upon the curve of the inferior thyroid artery opposite the sixth cervical vertebra, and gives off (1) *thyroid* branches upon the inferior thyroid artery; (2) the *middle cardiac nerve*, and two or three descending branches of *communication*, which pass in front of and behind the first portion of the subclavian artery to form a loop known as the *ansa Vicussenii*, and join the inferior cervical ganglion.

The *inferior cervical ganglion* lies below the transverse process of the last cervical vertebra and upon the neck of the first rib, and may be seen just above the first portion of the subclavian artery between the origins of the vertebral and superior intercostal arteries, and behind the inferior thyroid artery. It receives *communications* from the 7th and 8th cervical nerves, and from the middle cervical and first thoracic ganglia. Its branches of *distribution* are two filaments to the vertebral artery, branches to the subclavian artery, and the *inferior cardiac nerve* to the deep cardiac plexus. (From Heath's *Practical Anatomy*.)

11. The *pituitary body* is a ductless gland, situated on the sella turcica of the sphenoid bone, under cover of the diaphragma sellæ; in the center of this latter is an opening for the passage of the infundibulum. It consists of two lobes, the anterior is the larger and belongs to the digestive tract; the posterior, which belongs to the nervous system, is connected with the tuber cinereum of the brain by means of the infundibulum.

12. "The *semilunar valves* guard the aortic and pulmonary openings. They consist of three semicircular folds attached by the convex margin to the wall of the artery at its junction with the ventricle, and are formed by a reduplication of the lining membrane strengthened by fibrous tissue. In the centre of each free margin is a little nodule, the corpus Arantii, the three meeting in the centre when the valves are closed. On each side of the corpora Arantii is a thin semilunar marginal surface, where the fibrous tissue is absent, called the lunula; these surfaces come in contact when the valves close."

The *tricuspid valve* is situated in the right ventricle at the auriculo-ventricular orifice, and prevents the passage of blood into the auricle during the ventricular systole. It consists of three flaps or cusps, connected by their bases to the auriculo-ventricular orifice; their free margins and lower surfaces give attachment to the chordæ tendinæ which connect them with the muscoli papillares. The valve is formed of a duplicature of the lining membrane of the heart, strengthened by connective tissue.

The *ileocecæ valve* is on the left side of the cecum, at the opening of the ileum into the colon. It consists of two semilunar segments, the upper of which is horizontal and is called the ileocolic; the lower is vertical, and is called the ileocecal. On each side is a ridge called the frenum.

The *valve of Vieussens* is a thin layer of white matter stretched between the two superior processes of the cerebellum and connected with the lingula of the superior vermiciform process. It forms the roof of the upper part of the fourth ventricle.

The *epiglottis* is a thin, leaf-shaped lamella of fibro-cartilage situated behind the tongue and above the larynx. Its free extremity is broad and rounded; its lower part is attached to the thyroid cartilage.

PHYSIOLOGY.

1. "The normal stimulus to muscular contraction during life is an impulse passing from the central nervous system along the nerve which ends in the muscle fibres. In a muscle-nerve preparation, the muscle contracts either when it is stimulated directly or when the stimulus is applied to the nerve. It was formerly supposed that even when the stimulus was applied to the muscle itself the latter did not respond directly to the stimulus, but contracted because this acted upon the nerve fibres running within the muscle. There is no doubt, however, that muscle can be excited to contract independently of impulses reaching it along nerve fibres (independent irritability of muscle).

Curare paralyzes the endings of nerve fibers in a muscle, and, when it is injected into an animal, stimulation of a motor nerve has no effect upon the muscle, whereas direct stimulation of the muscle causes it to contract." (Bainbridge and Menzies' *Essentials of Physiology*.)

2. *The fetal circulation*: "The arterial blood coming from the placenta to the fetus travels along the umbilical vein to the liver. After giving off several branches to the left lobe it divides into two streams, the larger joining the portal vein and thus entering the liver, the smaller passing directly into the inferior vena cava through the *ductus venosus*. In the inferior vena cava the blood carried by the hepatic veins and *ductus venosus* mixes with the blood which has circulated through the lower extremities. On entering the right auricle the blood of the inferior vena cava is directed by the Eustachian valve, through the foramen ovale into the left auricle, and from thence into the left ventricle. The left ventricle forces it into the aorta, and it is then distributed to the head and upper extremities, a small quantity only passing into the descending aorta. The blood which has circulated through the head and upper extremities returns to the heart along the superior vena cava, the blood then passing into the right ventricle and pulmonary artery. A small part of the blood in the pulmonary artery is conveyed to the lungs, but the major part passes through the *ductus arteriosus* into the aorta at the commencement of the descending portion. This blood is distributed to the lower extremities, a certain portion of it entering the hypogastric arteries and being conveyed to the placenta." (Ashby's *Physiology*.)

The Respiration of the Fetus.—"Unlike the circulatory organs, the fetal mechanism of respiration does not begin its work until after birth, when for the first time it can have air with which to inflate the lungs. The fetus, however, breathes, but oxygen and not air, and it excretes the carbon dioxide, inevitable product of its tissue-metabolism, into the maternal blood instead of into the atmosphere. Fetal respiration, then, is wholly internal respiration. The respiratory mode of mammalian embryos is practically the same as that of fishes, for although the former have no proper gills, still the gases interchange (through layers of maternal and fetal epithelium) between the liquid blood of the embryo and the liquid environment. In this case the environment is the circulation in the placenta of the mother. The fetal chorionic villi and the blood-filled sinuses of the decidua serotina of the placenta, extending inward from the uterine fundus, interknit with the greatest closeness. Thus, the villi of the fetal circulation, made up largely of capillaries, are quite surrounded by the large blood-sinuses filled with maternal blood. The circulation of the fetus, then, exchanges its two respiratory gases through the walls of capillaries just as does the adult circulation, save that instead of exchanging them with the alveoli the fetal blood takes its oxygen and excretes its carbon dioxide second-hand, as it were, from and into the maternal circulation."—(Dearborn's *Physiology*.)

The Digestive System.—"Very little is definitely known concerning the activity of the various glands connected with the alimentary canal in the fetus. A few observations have been made which show that the salivary and gastric ferments are present at birth, and according to some at a much earlier period. Trypsin also is stated to be present in the pancreatic secretion in the second half of pregnancy, and the fat-splitting ferment is in most cases present at birth. The amylopsin of the pancreatic secretion does not, however, appear till some time after birth. The large size of the fetal liver has caused it to be credited with important functions. It assumes its characteristic structure at about the fifth month, and at the same time begins to secrete a greenish-colored bile. The latter collects in the large intestine and forms the greater part of the meconium, in which bile-acids and bile-pigments can be shown to exist. It also collects in the gall-bladder, which is sometimes found fully distended in the full-term fetus. Before the secretion of bile no meconium is found in the intestines, but after the fifth month it collects in large quantities. Analysis shows that it contains, in addition to the bile-pigments and salts, a considerable amount of mucin, and secretions from the various intestinal

glands, more especially that of the pancreas. The presence of lanugo, vernix caseosa and epidermal cells within it confirms the opinion that the liquor amnii is swallowed at intervals by the fetus. In cases of occlusion of the bile-ducts the meconium is of a brownish color. In addition to its function in secreting bile, it is generally supposed that the glycogenic function of the liver is early established, and that the large size of the viscus is associated with the presence of large amounts of sugar in the tissues of the fetus. Some glycogen can be detected in its substance at birth. The principal waste substances, which result from the nitrogenous metabolism of the fetus, are excreted by means of the placenta into the maternal circulation, but a small amount of urea and uric acid is also passed with the secretions of the kidney into the bladder, and is thence probably passed at intervals into the amniotic fluid. That the bladder is frequently full during intrauterine life is proved by the familiar fact of the emptying of that viscus which so often takes place immediately after birth, but that any important excretory function is performed by the kidneys before birth has not been proved."—(Jellett's *Manual of Midwifery*.)

3. *The functions of the cerebrum* are (according to Starr): To receive impressions from the various sensory organs as conscious perceptions; to associate these various simultaneous perceptions into a mental image or concept; to retain these concepts as memories so that objects can be recognized or recalled; to give expression to thought in action and in speech; to restrain the flow of thought and to inhibit or control automatic and reflex acts.

Functions of the optic thalamus.—"The fibres that go to the occipital cortex have to do with vision; those that go to the temporal lobe have to do with hearing; the optic thalami have a probable relation to the expression of emotions; it is probably a primary center for sensations of touch, muscular sense, and perhaps for smell and taste."—(From Dana's *Nervous Diseases*.)

Functions of the cerebellum.—"Equilibrium and co-ordination of muscular movements."

4. *The function of the calcium salts in the body* is to give rigidity to the bones.

Milk supplies the largest amount of calcium salts at the time of life when they are most needed.

5. *Absorption of carbohydrates*.—"During digestion the greater part of the carbohydrate of the food is converted into the glucoses. These are comparatively small molecules which are readily dissolved, and easily passed through the columnar cells into the portal vein radical which lies beneath. It is possible that some maltose may be absorbed by the columnar cells, and that during its passage through those cells it is converted into dextrose before it enters the portal vein radicals. It is possible that in these columnar epithelial cells the glucose, which is being absorbed, is linked to the cell protein, and that, further down the cells, this loosely combined substance is split into two, the dextrose passing into the portal vein radical and the protein molecule remaining intact in the columnar cells and ready to combine with fresh glucoses to be passed through the cells. A small proportion of the dextrose, which is carried to the liver, goes on unchanged to the tissues to be assimilated, but the greater portion of the absorbed glucose on arriving at the liver is stored there by the liver cells as glycogen."

Absorption of fat.—"Fat is not absorbed as fat, but as glycerin and fatty acid or soap. It is generally accepted that the fatty acid set free in the intestine is dissolved by the bile salts, and in this way, together with the glycerin, is absorbed by the columnar cells, but that during absorption a lipase which is contained in the columnar cells re-synthesizes, by reverse action, the glycerin and fatty acid. In this way minute fat particles are found near the bases of the columnar cells, and these may be demonstrated by staining with a 1 per cent. solution of osmic acid. The fat globules are further taken up from the columnar cells by some of the lymphocytes, which are capable of exhibiting amoeboid movements, and which are found in the lymphoid tissue between the columnar cells and the central lacteal. The fat is then deposited in the central lacteal by these amoeboid cells, and in this way it gets into the general lacteal stream, and thence into the thoracic duct. The bile salts, which have been absorbed

by the columnar cells, in all probability get into the portal vein radical, and in this way are taken back to the liver to be excreted again in the bile. After a fatty meal minute globules of fat may be demonstrated in the blood plasma of an animal; but they disappear rapidly, possibly existing in a soluble and invisible form absorbed to the blood proteins before they are deposited in the fat depots of the body."

Absorption of proteins.—"The view previously held with regard to the absorption of protein was that during digestion protein was finally converted into peptone, and the peptone so produced was absorbed by the columnar cells over the villi, and built up again by these cells into serum albumin and serum globulin, the chief proteins of the blood plasma. The view generally accepted now is that protein is completely hydrolyzed into the cleavage products known as amino-acids in the intestine; and it is these amino-acids which, being smaller molecules than the original protein, readily pass through the striated free border of the columnar cells over the villi and so get into the protoplasm of these cells. Here a synthesis takes place, and some simple and aromatic amino-acids are converted by the columnar cells into serum albumin and serum globulin, the native proteins, and this protein is conveyed to the tissues."—(Lyle's *Manual of Physiology*.)

6. When blood is withdrawn from the blood-vessels of the living body, it first becomes viscid, then sets, and is converted into a jelly-like mass. This is due to the formation of fibrin. The jelly contracts forming the clot; and at the same time the serum is squeezed out from the clot. Various circumstances and conditions will hasten or delay the process of coagulation. In man, the blood generally becomes viscid in from two to three minutes; it forms the jelly-like mass in from five to six minutes; a few minutes later the serum begins to appear, and the whole process is completed in from twenty-four to thirty-six hours. The clot then floats on the serum. The process is thus summed up by Halliburton: In the plasma a proteid substance exists, called Fibrinogen. From the colorless corpuscles a nucleoproteid is shed out, called Prothrombin. By the action of calcium salts prothrombin is converted into fibrin ferment, or Thrombin. Thrombin acts on fibrinogen in such a way that two new substances are formed: one of these is unimportant and remains in solution; the other is important, viz., Fibrin, which entangles the corpuscles, and so forms the clot.

7. "Obstruction of the bile ducts (by parasites, foreign bodies, impaction of gallstones, inspissated bile or mucus, pressure from tumors of liver or pancreas, etc.) prevents the bile from entering the duodenum. The bile then enters the blood current and is carried throughout the body, thus producing the characteristic yellow tint of skin and mucous membranes, and the deep-yellow color of the urine."—(Scott's *State Board Physiology*.)

8. "The normal stimulus which excites the flow of the gastric juice is the presence of food in the mouth. If the esophagus of a dog is divided and the two ends are brought to the surface and fixed there, food may be masticated and swallowed by the animal, but none will reach the stomach. This sham feeding is followed by the secretion of gastric juice at the same time and in the same way as if the food reached the stomach. This fact points to the probability that the first secretion is due to a nervous reflex, a presumption which is further supported by the observation that, as in the case of saliva, even the sight or suggestion of food is followed by the appearance of gastric juice. The nervous nature of the stimulus is proved by the effect of division of both vagus nerves to the stomach, after which no secretion takes place on sham feeding or on showing food to the animal. Further proof is obtained by the production of secretion as a result of stimulation of the vagus. The nerve is divided in the neck, and four days later, when the cardio-inhibitory fibres have degenerated, the distal end of the nerve is stimulated by a tetanizing electric current. Five minutes after the commencement of stimulation the gastric juice begins to flow."—(Bainbridge and Menzies' *Essentials of Physiology*.) In addition to this, it should be added that a small amount of gastric juice is also secreted in response to a chemical stimulus excited by the presence of food in the stomach.

9. The *respiratory quotient* is the relationship be-

tween the volume of carbon dioxide which leaves the body in respiration and the amount of oxygen taken into the body and not reappearing in the expired air. It is generally represented by the equation

$$R. Q. = \frac{CO_2}{O_2}, \text{ and ordinarily this is } \frac{4}{5} = 0.8.$$

10. *Water is discharged from the system* as follows: By the kidneys, about 46 per cent.; by the skin, about 30 per cent.; by the lungs, about 20 per cent.; and by the large intestine, about 4 per cent.

11. *Physiology of equilibrium.*—"The body is constantly held in a state of balance, and no movement of any degree can be made in any part without a compensatory movement to preserve the center of gravity. The slightest variation in our position which would tend to the loss of balance is immediately perceived and immediately corrected. Furthermore, the balance is maintained by an interaction of visual sensations, labyrinthine impressions, and muscular sensations, all of which enter into this function, as can be seen by the disturbance of balance occasioned by double vision, or by labyrinthine disease, or by a loss of the muscular sense, as in locomotor ataxia. While consciousness takes cognizance of this complex matter of equilibrium, the primary centers which receive the impressions and regulate the activity that they arouse are located in the cerebellum. This is the great organ of equilibrium, and it therefore receives impressions directly from the eyes, from the semicircular canals, and from the muscles of the limbs. The most important impulses in the preservation of equilibrium, however, are derived from the semicircular canals through the vestibular nerve."—(Starr's *Nervous Diseases*.)

12. *The cornea* is not provided with blood-vessels. The capillary loops from the anterior ciliary vessels form a ring around the circumference of the cornea. Its nutrition is provided for by a system of lymph canals which are found in the substance of the cornea.

(To be continued.)

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

MEDICAL WAR MANUAL No. 5. LESSONS FROM THE ENEMY. By JOHN R. MCGILL, M.D., F.A.C.S. 262 pages. Illustrated. Price, \$1.50. Published by Lea & Febiger, Philadelphia and New York.

ANIMAL PARASITES AND HUMAN DISEASE. By ASA C. CHANDLER, M.S., Ph.D. 570 pages. Illustrated. Published by John Wiley & Sons, Inc., New York.

DISEASES OF THE HEART AND BLOOD VESSELS. By THOMAS E. SATTERTHWAITHE, A.B., M.D., LL.D., Sc.D. 323 pages. Illustrated. Published by Lemcke & Buechner, New York.

MODERN OPERATIVE BONE SURGERY. By CHARLES GEORGE GEIGER, M.D. 286 pages. Illustrated. Price, \$3.00. Published by F. A. Davis Company, Philadelphia.

PLAIES DU PIED ET DU COU-DE-PIED PAR PROJECTILES DE GUERRE. Par E. QUENU. 460 pages. Illustrated. Price, 16 francs 50. Published by Librairie Felix Alcan, Paris.

THE PRIMARY CAUSE OF SHOCK.

ADDITIONAL EXPERIMENTS INDUCED BY THE WAR.

By FENTON B. TURCK, M.D.,

NEW YORK.

SINCE the war has demonstrated that shock is such a vital question, I have been led to undertake this new series of experiments, not only to shed more light on the etiology of shock, but to assist in the work of the production of immunity.

The war reports show that the wounded are seldom in a state of shock at first, not until two to four hours or more after the injury, and that the immediate or nervous shock is comparatively rare, (Quenu¹, P. Santy²).

The opinion is gaining ground that shock is due to some poison formed as the result of the injury, rather than to a nervous affection. The shock concept embedded in the psychogenic mesh has entangled in the past even the laboratory worker. Goltz tapped animals over different parts of the body until they died and ascribed the death to nervous vasomotor paralysis. Gutsch³ also concluded the same from his experiments. Fisher⁴ made the clinical application of these and like experiments to the syndrome of shock, and in our country Mitchell, Morehouse, Keen, Crile, and others have so emphasized the brain-nerve idea of shock, that we have lost sight of other conceptions. The war has proved the "hopelessness of shock" (Gray⁵) considered from this neuropsychogenic standpoint. The escapement from the thralldom of a fixed idea is scientific research.

If we transplant burned or lacerated wound tissue from an injured animal to another animal the latter dies from shock, while the original animal, with the burned tissue removed, survives. It must be removed early because injured tissue promptly begins to undergo self-digestion (autolyze). If the autolyzed injured tissue cells or their products are injected into an animal it dies from shock the same as the animal with the original injury (see protocols). Products of the nature of toxic albumins are formed by self-digestion of the tissues very rapidly; they give the biuret reaction and show the autolysis on microscopic examination, and when absorbed are deadly poisons.

These observations made in the opened abdomen of the animal in shock from injury or from the injection of the tissue products, show that the action of shock is staged in the splanchnic area, especially the upper abdomen, stomach, intestines, and liver. Sections of these organs taken in the prog-

ress of shock indicated that these excretory and detoxicating organs receive the first brunt of the reaction we call shock. The nervous system does not enter into this reaction.

Falling blood pressure and temperature, metabolic failure and loss of ferments, alkaline bases, CO₂ and O are secondary results.

Following this line of investigation of shock naturally leads up to the production of immunity. This has been done by repeated increasing doses of the *homologous* autolyzed tissue so that a high degree of immunity against shock can be established without symptoms. Heat of high degree applied so as to influence promptly the splanchnic area materially increases the immunity against shock if used early after the injury. Several practical methods for the application of heat to affect the splanchnic area in shock, devised by the author in the early nineties, have been used with excellent results.*

Pirogoff's term "traumatic torpor" or "wound stupor" to express the phenomena to which we have given the misnomer "shock," which originated in England, would better have been retained. The latter name, according to Captain Frazer and Cowell⁶, is to be deprecated, and Berger and Vignes⁷ protest against the blanket term shock because it adds an element of mystery to what is already known. Nerves are not "jolted" into a state of exhaustion, but there is a definite biological status produced, and stupor or torpor expresses more accurately the toxic influence that exists in "shock."

Roux of the Pasteur Institute repeats that there never was a war in which epidemics were so rare

*The study of surgical shock by the writer began in 1891 and 1892, during an interne service at the Alexian Brothers Hospital. There the service was largely emergency in character, and abdominal wounds and injuries were very frequent, often those in which the abdominal viscera were exposed. We at this time observed that when the abdominal viscera were exposed shock was produced even though there was very little hemorrhage; as in other extensive injuries, such as mangled limbs caught in machinery, the shock did not appear, as a rule, until two to five hours after the injury. At this time we found that heat applied within the splanchnic area especially was very effective in reducing shock. This led to the experiments on animals on the biology of shock, and further comparative observations in surgical cases. Through these it was found that not only acute, but certain chronic conditions were associated with phenomena similar to those found in shock. These investigations were published with the experimental data in 1894, 1895, 1896, 1897, 1900, 1903, 1906, etc., on up to the present time.

For instance, we found that peptic ulcer occurred as a result of autolysis, a chemical poison in the nature of a proteose resulting from the self-digestion of this injured tissue. More recent investigations on the biology of shock have been conducted under the Pearson-Dunn Research, and lately in my own research laboratory.

as in the present one, and he explains that these alarming conditions are avoided only by utilizing the protective measures prescribed by science. This achievement of preventive medicine stands out in bold contrast to the unparalleled prevalence of shock, of which Archibald, McLean, and others⁷ have despairingly complained, as the "hopelessness of shock." (Gray⁴.) Bernard⁸, in his lectures on "The Present Methods in Military Surgery" shows that in other wars (Russo-Japanese and Balkan) wounds were caused by smooth bullets, but in the present war by shells, projectiles, and grenades resulting in a mangling of the wounds and much destruction of tissue.

Shock is inevitable in all wounds, as Edward Johnson⁹ contends, but wounds of the thigh, buttocks, and trunk give the greatest degree of shock (Gray), and shell wounds of these parts, according to Hinds¹⁰ are of most frequent occurrence. The explanation is obvious, for the reason that when there is an explosion a man naturally crouches forward and the exposed parts are hit. Absorption from the wounds of the lower extremities and trunk possibly more readily affects the abdominal area, where the shock reaction takes place, because of the more direct connection by the vascular, lymphatic, and diffusion routes, by which the rich supply of toxic autolyzed cellular products is conveyed.

Bernard⁸ shows the limitation of therapeutics in shock shared by all military surgeons. He says "In case of shock, heat, saline, and adrenalin, camphor oil, and morphine are all used if required." The tourniquet and "débridement" (this consists of opening the wound and removing all dead and mangled tissue) are used for the purpose of stopping hemorrhage and infection. Are these not, in the light of experimental findings, chiefly means for the prevention of shock?

Pirogoff¹¹ expressed surprise when he removed a six-pound cannon ball from the thigh of a soldier that, though the femur was fractured, the soldier walked and experienced little or no shock. At the same time he notes that a heavy bomb passed close to the body of another soldier without touching him and yet death ensued. On postmortem examination "no apoplexy" was found, but the brain was said to be congested. No report was made of the finer changes of the other organs. This might be taken to indicate that shell shock may be of psychogenic origin, but in my experimental work it was found that placing an animal close to a centrifuge revolving at great speed to imitate a passing shell or ricochet, resulted in small lesions or multiple wounds in every organ of the body. Postmortem examination showed the same lesions in the liver and upper splanchnic area as are found in ordinary wound shock. Microscopic examination showed the usual findings in shock. The brain and spinal cord suffered but little from the shock. (See protocols "Shell Shock," figs. 24 to 28.)

Bauer¹² has recently made a careful clinical study of shell shock and concludes that a "medullary commotion effect" is produced on all the organs and tissues of the body, such as heart, liver, stomach, intestines, and bone marrow, causing purely inhibitory functional disturbance, these being quite independent of any psychogenic mechanism.

Disseminated areas of microscopic lesions throughout the body in experimental "shell shock"

in the aggregate, the author estimated, may produce an effect similar to that which occurs as the result of gross distinctive injuries inflicted by shrapnel. The same autolysis and intoxication follow as in gross lesions.

In 1893¹³ I made application of severe irritants, chemicals such as silver nitrate, to the gastric mucosa and found that it produced only a local reaction.^{15,16} Even trauma of the mucosa effected by the use of a wire brush healed promptly without shock symptoms,¹⁷ while simple exposure of the peritoneal side of the stomach to the cool air produced an area of definite, progressive congestion of the upper splanchnic vessels which could be observed with a magnifying lens until death supervened, and which were accompanied with the symptoms of shock, fall in blood pressure and temperature and depression of the vital functions.¹⁴⁻²⁰⁻²³ Rough handling or bruising the tissues only shortened the time of the development of shock symptoms.²⁵ Injury to the limbs of the trunk, if left unprotected, resulted in shock, in hepatic, pyloric, duodenal, and gastric congestion, and in death. It appeared that some protective process prevented shock when the injury occurred on the inside of the stomach, while injuries inflicted on the peritoneal or other parts of the body (parenteral), seem to leave the organism without protection, defenseless against the reaction.¹⁶⁻³⁰

Local injuries to the peritoneal side of the stomach or peripheral injuries were similar in effect to those produced by injections of proteoses,¹⁶ or such as occur when tissue cells undergo disintegration.²⁸ All the cells of the body contain ferments, proteases, and there are also ferments forming from extravasated leucocytes which cause proteoses to form.

The writer injected peptones obtained from the dilated stomach into the peripheral as well as the splanchnic veins.^{14,16,30} This seemed to cause a condition of shock and death similar to that accompanying cellular destruction resulting from exposure of the viscera to air, a mechanical trauma of the trunk or limbs, burns, and other injuries.

The question put forward in earlier papers by the writer was, "Why do the patient's physiological activities continue to fall after the irritation has been removed?" "There is a loss of function and depression of cellular activity." "Experiments seem to indicate molecular cellular changes are produced so that the side chains in the albumin molecule are altered."²³ As the result of injury some poison of the nature of a peptone seemed to be formed which I termed the "shock toxin."¹⁴

The rough handling of the viscera exposed to the air causes desquamation and disintegration of the endothelium lining the peritoneal cavity just as burns affect the skin. I took the resulting fluid or serum with the cellular products from the peritoneal cavity of the shocked animal and injected it into normal animals of the same species of the same litter, with production of similar shock symptoms and death.²⁸ Furthermore, the injection of this fluid taken from the peritoneal cavity with the disintegrated tissue caused the same train of shock symptoms as those produced by the injection of peptones from the stomach.^{23,16,28}

*An attempt was made to separate the toxic moiety from the proteoses derived from dilated stomachs by fractional coagulation at various temperatures.

Prolonged anesthesia in animals caused identical conditions which, as I have shown, are not due directly to the toxin of the anesthetic used, but to the cellular products of disintegration, so-called "metabolic changes."²⁹

The injection of emulsions of homologous muscle cells that had undergone autolysis,³¹ the autolysis being determined by histological examination of the muscle cells, caused symptoms of visceral dilation to occur similar to those which often accompany shock. So also did the injection of fatigue products obtained from the stomach muscles of homologous animals.³¹ Serum added to the muscle cells lessened the toxic reaction, yet shock was produced when homologous serum, from animals which had been in shock, was injected. The autolyzed cells that were disintegrated in the serum were apparently responsible for the occurrence of the shock.³²

Homologous emulsions made from the mucous membrane³³ of the pyloric end of the stomach of a dog and injected intravenously into a dog caused necrosis of the pyloric duodenal area. These pyloric lesions were frequently observed in shock produced in animals by trauma, burns, or surgical trauma or by protein injections.

In 1905 guinea pigs under morphine were shocked by the repeated faradic current resulting in the syndrome "wound shock" and death. The viscera and skin were removed, the muscle tissue was ground up, and the extract intravenously injected into rabbits' ears produced the same shock, falling temperature, visceral congestion, and death.

Other toxins than those formed from autolyzed tissue cells, such as diphtheria toxin, when injected into the mesenteric vessels did not give the same pathological picture as that produced in shock, or when pure peptones were injected.³⁰

My general conclusion has been that the phenomena of shock from all my previous experimental and clinical observations were shown to be due apparently to toxic proteoses formed by the digestion of injured tissues, that is, "shock toxins."³⁴ Natural immunity observed to a greater degree in some animals than in others led to methods of producing immunity against shock. Some suggestive observations were made of the antibody formation by injecting sublethal doses of homologous cellular muscle extract.³ We cannot consider shock as it occurs in this war without reference to the rôle of bacteria. It is claimed that "all war wounds contain germs from the first."

The relation of infection to shock is unique. The autolyzing tissue of a wound furnishes a rich soil for bacterial growth. Many microorganisms have no direct pathogenic properties,³⁵ but they increase the digestion (autolysis) of the devitalized tissue and a greater amount of toxic proteoses are formed aside from any toxin in the germ itself. *Bacillus coli communis*, though producing no extracellular toxin hastens autolysis of the injured tissue cells.³²⁻³³ Following this work on fetal liver cells added to a non-virulent culture of the *Bacillus coli* also *Bacillus welchii*, I later injected into animals fresh fetal cells incubated thirty minutes with non-virulent *B. coli* and it caused shock symptoms and death, while the animals injected with *B. coli communis* or the fresh fetal liver cells alone showed no marked symptoms, and the animals did not die.

EXPERIMENTS

Animal experimentation in shock is most valuable for an intelligent understanding of the treatment of battle wounds as they exist in this war. It enables one not only to produce practically parallel conditions but to establish a biological status which is most essential to a correct diagnosis of such wounds and the treatment to be employed. The following attempts to duplicate the conditions of "shell wounds," burns, and "shell shock," with or without ricochet, are valuable in the elaboration of the author's previous work.

In this series of experiments the shock symptoms, falling temperature, loss of reflexes, failing circulation and respiration, ending in death, are so manifest that they indicate sufficiently the true shock syndrome. The use of anesthetics was unnecessary when shock was established, because of the "stupor" due to the secondary effects of the poison which is usually absorbed from the wound tissue. Injected animals receiving the "shock poison" died promptly with or without an anesthetic.

Series I.—In the first series one or both legs of the animals were constricted with elastic ligatures to shut off the circulation. The thigh muscles were then bruised and the tissues mangled peripheral to the ligatures, thus liberating and disintegrating cells without hemorrhage. After variable periods, depending on the character and degree of the injury, cellular autolysis occurred. In the first group of experiments the free autolyzed tissue cells and their products were allowed to enter the circulation or tissues by releasing the constricting ligature. On releasing the ligature, but slight hemorrhage, due to the prolonged constriction, occurred. In some of the experiments the free substances evolved in the injured leg were massaged upward into the organism. This procedure caused shock symptoms promptly and severely, and in many cases almost dramatic in character, as evidenced by marked trembling, fall in blood pressure and temperature, rapidly failing circulation and respiration, and finally death.

Controls.—If the ligature was kept intact and absorption absolutely prevented no definite shock symptoms developed from the mangled tissue. Antiseptics and astringents were injected above or at the wound juncture above the ligature line; amputation of the bone was performed, with recovery.*

In another group in this same series the elastic ligature was not released, but portions of the muscle tissue were removed and weighed, the substance pressed out with a meat press, and injected intravenously into the same animal; or the tissue juices secured in situ from the leg, were diluted with salt solution or plain sterile water and injected into either the upper or lower veins of the same animal or one of the same species. The same shock syndrome developed here as in the series where the ligature was released and the products were massaged into the body circulation.

Series II.—Instead of injecting the autolyzed cells into an animal, the mangled muscle tissue from the thigh was inserted or transplanted into the

*There is a limit to this control, because of absorption at and above the ligature junction where autolysis takes place; and also no ligature can completely stop the diffusion of toxic products.

thigh (intramuscular) of another homologous animal, which invariably resulted in death from shock of the host (animal receiving the transplanted muscle). Amputation of the original denuded bone in the original animal was usually followed, with ordinary care, by recovery of the animal.

Series III.—In the third series of experiments fresh muscle taken from a normal animal was placed in an incubator or on ice under antibacterial conditions and allowed to autolyze. When autolysis was sufficiently advanced, as determined microscopically by the loss of nuclear staining, and also by the biuret reaction, the tissue was weighed, ground up in a mortar with plain sterile water or salt solution (the former being more effective), and the supernatant fluid was injected into an homologous animal.

Lethal doses caused immediate death within three minutes; with smaller doses the complete shock syndrome appeared in the classical order and death ensued in a few hours; with minimum dosage shock symptoms occurred but recovery took place.

Series I.

EXPERIMENT I.—*Cat No. 1* (Male). Weight, 4,300 gm.; time, 9.15 A.M.; temperature, 39.5° C.; temperature of room, 21° C.; anesthesia, ether.

9.30 A.M.—Temperature after etherization, 38.5° C. Animal placed on top of the radiator to keep warm. Esmarch pressure on internal iliacs and abdominal aorta to keep blood from lower extremities. Thigh and gluteal muscles bruised. Toe was cut to show that the blocking of the circulation was effectual.

10.15 A.M.—Temperature (esophageal and gastric), 36° C. (This change in method of taking temperature was made necessary by the cutting off of the circulation.)

11 A.M.—Temperature (intragastric), 35.5° C. 11.20 A.M.—Temperature (intragastric), 35° C.

Esmarch restriction released.—The bruised tissue was occasionally massaged to simulate condition brought about in transporting a shocked patient, thus increasing liability of bruised tissue substance getting into the circulation.

11.40 A.M.—Temperature (intragastric), 34° C. Anesthesia removed. 1.55 P.M.—Temperature (intragastric), 35° C.

Massage of lower limbs to carry products of disintegration into circulation. This was followed by the rapid failing symptoms of shock.

3 P.M.—Temperature, 32.5° C. Mucous membrane of the mouth pale and cold. Nose pale and cold. Ears cold.

4 P.M.—Temperature (intragastric), 32° C.; (rectal) 32° C. 5 P.M.—Temperature (rectal), 31.8° C. 6 P.M.—Temperature (rectal), 30° C.

Animal died. Abdomen opened. Hepatic lobules well marked. Congestion of the pyloric region. Lower small intestines and colon pale. Post-mortem examination showed the usual pathological findings of shock. (See Figs. 3 and 4.)

EXPERIMENT II.—*Rabbit No. 5.* Weight, 1,400 gm.; time, 9.15 A.M.; temperature, 40° C. before the anesthesia.

9.15 A.M.—(This animal had previously had injections of sheep cells.) Left leg tied off above the great trochanter as before. Legs mangled and bruised.

10.15 A.M.—Stopped anesthesia. Released the constriction and allowed the products to enter the blood. Animal became depressed, so that no anesthesia was necessary.

11 A.M.—Difficult shallow breathing; rapid heart; temperature, 35° C.

12.45 P.M.—Animal died.

Post-mortem examination showed the liver, pyloric end of the stomach, and small intestines congested. (See Figs. 5, 6, and 7.)

EXPERIMENT III.—*Rabbit No. 2.* (Female, pregnant.) Weight, 1,200 grams; time, 1.30 P.M.; temperature, 39° C.; no anesthesia.

1.30 P.M.—Injected 2½ c.c. of autolyzed rabbit meat substance into the ear vein. Before injection the rabbit was very active.

2 P.M.—Animal showed signs of apathy and shock. 2.30 P.M.—Eyes were dull, anemic; gums were pale. Rabbit took no interest in surroundings.

3.30 P.M.—Apathy so great that hind legs could be pulled back and they would remain in this position, although no paralysis was present. Respiration was shallow. Temperature began to fall as the anemic appearance of the gums became manifest. Eyes became dull. Reflexes diminished to touch. Great muscular debility and relaxation of the extremities. Pulse rapid and feeble. Greater insensibility to all forms of stimuli is manifest as shock symptoms continue. Sudden jarring of the animal arouses it and proves that it is not unconscious. As soon as left undisturbed it relapses into an indifferent attitude without any apparent interest in the surroundings. A normal rabbit placed beside the shocked animal demonstrates the marked differences in activity and behavior. By comparison a high degree of pallor of the mucous membrane of the mouth, conjunctivæ, and nostrils, which are blanched almost white, is observed. Pulse continues weak and rapid; breathing is difficult and labored. Ears are cold to the touch, as compared with those of the normal rabbit. Proximity of the normal rabbit creates no interest in the shocked animal; it rests in the usual indifference of shock. The animal does not respond to pinching, pricking, heat, or cold, except in a slight degree, moving to the side when the stimulation is excessive. Animal placed in cage. Refuses to drink water; remains in same position as placed. 9 P.M. rabbit died.

Record of Temperature, Rabbit No. 2.—1 P.M., before injection, 39.4°; 1.30 P.M., injection, 39°; 2 P.M., 38.5°; 2.30 P.M., 38°; 3 P.M., 37.5°; 4 P.M., 37°; 5 P.M., 37°; 5.30 P.M., 36°; 9 P.M., animal died, 34°.

Post-mortem findings: Stomach, pylorus, duodenum, and upper small intestines show usual congestion, liver markedly congested.

EXPERIMENT IV.—*Rabbit No. 3.* Weight, 1,500 gm.; time, 4.30 P.M.; temperature, 39.4° C. before anesthesia and injection; temperature of room, 17° C.

Procedure.—Opened abdomen of rabbit No. 3 under chloroform anesthesia. Examined liver and upper splanchnic area. Injected a drop of the autolyzed muscle substance from rabbit No. 1 into the liver. There was a slight turgescence reaction. Injection of 1 mm. of the same substance into the gastric vein, branch of the right epiploic vein. Shock symptoms soon developed, but gradually.

Observations.—Reaction was not sudden as in strict anaphylaxis, but soon the respiratory and cardiac symptoms of shock developed. The symptoms of true traumatic shock developed in the usual gradual, orderly manner. The splanchnic vessels became hyperemic, then turned to a purplish hue, with turgescence of the veins which became tortuous.

Anesthesia removed as soon as shock symptoms were established. Animal came out of anesthesia promptly, but shock symptoms soon supervened, as in animal No. 2 which had no anesthesia.

Vessels in the upper tract were more deeply congested than those in the lower. The gums, eyes, and nostrils all became pale as the ears turned cold. Muscular debility developed. Placing the animal under a bell jar to keep it warm, and also so that it would receive more carbon dioxide and less oxygen, did not prevent the progress of shock symptoms.

The viscera were covered and held by sutures in the abdominal wall arranged so that the abdomen could be opened at intervals for inspection. Although no anesthesia was in use at this time, the animal showed no signs of pain during these procedures. A condition of apathy developed and sensations were abolished.

Conclusion.—As the symptoms were not so explosive or violent in the whole course, it seems as if the autolyzed muscle has passed over into a less toxic moiety.

It seems evident that the introduction of 1 c.c. instead of 2½ c.c. produced a slower shock, less violent symptoms, but there was a steady progress of the symptoms which led to the same result. Finally, the respirations became more labored and the animal died after a few convulsive efforts to get air.

Temperature Record, Rabbit No. 3.—4.30 P.M., before

anesthesia and injection, 39.4° C.; 5 P.M., 38.2°; 5.30, 37.8°; 6 P.M., 36.2°; 6.30 P.M., 36°; 7 P.M., 35.8°; 8 P.M., 35.2°; 8.45 P.M., 34.1°; death of animal.

Post-mortem Findings.—See pathological description. Also note Figs. 18, 19, 20.

EXPERIMENT V.—*Rabbit No. 4.* Weight, 1,800 grams; time, 3.30 P.M.; rectal temperature, 39.5° C.; room temperature, 23° C.; anesthesia, chloroform continued with ether.

3.30 P.M.—Leg bandaged up to crotch and over the gluteal region, sufficiently tight to shut out all circulation from the entire leg, producing an ischemic condition of the tissues. Strong elastic Esmarch ligature above the neck of the femur and gluteal region. With strong, dull, flat forceps the tissues are crushed, mangled, and allowed to undergo autolysis in situ in the leg. Then the ligature is removed, the fur is removed, and the tissues are covered with a rubber bag.

Temperatures (rectal): 4.25 P.M., 39° C.; 5 P.M., 38.5° C.; 5.40 P.M., 37.5° C.

An extract was obtained of the mangled muscle tissue by the addition of salt solution, injecting 1 c.c. at 6 P.M. Anesthesia is removed.

The animal on emerging from the ether made some effort to jump, but soon lapsed into the usual nonchalance of shock symptoms. Reflexes more or less responsive to stimulants. Aroused by sudden approach.

Temperatures: 6.40 P.M., 36.2° C.; 7 P.M., 36° C.; 7.45 P.M., 35.8° C.; 8.20 P.M., 35.2° C.

Animal has been out of anesthesia two hours and forty-five minutes. There have been no pain symptoms. While it shows signs of activity when aroused, it readily lapses back into the shock symptoms. Ears are cold to the touch, there is blanching of the surface. Sudden turning off and on of the light causes sudden incoordinated struggles, followed by relapse into shock symptoms.

9.50 P.M.—Temperature, 35° C. Injected ½ c.c. of muscle products into the ear vein.

10.15 P.M.—Trembling marked over entire body; reflexes diminished; becomes more difficult to arouse the animal. Turning on and off of the light produces no effect.

10.45 P.M.—Injected 1½ c.c. into the ear vein.

11 P.M.—Animal now in profound shock.

12.15 P.M.—Incision made in abdominal wall for hasty inspection of liver and pyloric region before death. This region was found to be congested, while the lower portions of the intestinal tract were pale and bloodless.

12.30 P.M.—Animal died in profound shock, abdominal wound having been closed after above observation.

Post-mortem findings showed the usual splanchnic congestion.

EXPERIMENT VI.—*Cat No. 3.* Weight, 4,200 grams (large male); anesthesia, chloroform, continued with ether; time, 2.45 P.M.; rectal temperature, 40° C.; room temperature, 18° C.

Crushed the thigh and gluteal muscles with heavy pile forceps, without breaking skin or fascia, but with sufficient energy to excite leucocytes to wander into this area, with the idea of increasing muscle heterolysis by calling forth a greater amount of leucoprotease production before tying the leg with rubber ligature.

3.30 P.M.—Applied the elastic ligature and a cut of the sole of the foot showed all circulation was shut off by the ligature.

3.45 P.M.—Temperature, 35.5° C. Continuation of the crushing process, but not breaking the skin or fascia.

4 P.M.—Introduced instrument through small opening through the skin and mangled the muscle tissues under the fascia. *No bleeding.* Removed by excision 30 grams of the thigh muscle tissue. Put this in meat press and gently pressed out blood. Put tissue in press again under greater pressure to force out muscle plasma and products. This was to secure more of the autolyzed muscle substance than of blood serum, as the latter may interfere with the reaction.

4.30 P.M.—Injected 5 c.c. of this squeezed out muscle substance into the opposite femoral vein.

4.40 P.M.—Temperature, 33° C. The animal trembled, the heart was rapid and weak, and there was apparent fall of blood pressure with the fall in temperature. The head was kept low and the animal tipped up to keep the blood from filling the splanchnic area, as advised by

many clinicians. This did not prevent the failing symptoms, although it seemed to lessen the degree.

5 P.M.—Injected 2 c.c. of the extracted muscle fluid. Marked trembling followed promptly.

6 P.M.—Temperature, 32.2° C.

6.30 P.M.—Injected 2 c.c. of the extracted muscle fluid.

6.50 P.M.—Temperature, 31.2° C.

7 P.M.—Opened abdomen to inspect with lens the upper splanchnic area. The congestion observed in this area (liver, stomach, and duodenum) was fairly well marked, but in the lower splanchnic area there was pallor with the usual appearance seen in shock. Abdomen kept closed except for a moment of inspection.

7.45 P.M.—Animal died.

Post-mortem examination revealed the pathological findings of shock as shown in the illustrations.

Series II.

EXPERIMENT VII.—*Cat (Black; male).* Weight, 2,523 grams; temperature, 40° C. (rectal).

First Twenty-four Hour Period.—9 P.M.—Under anesthesia, upper and inner sides of the left leg were shaved. Under strictly antiseptic conditions ground muscle tissue taken from mangled leg of a cat which had been in complete shock was inserted or transplanted in between the muscle substance of the leg. With the blunt end of the knife and forceps the muscles of the leg were separated, avoiding laceration or hemorrhage, and 40 grams of ground muscle tissue was packed in its leg. The incision in the leg was then sutured. Cat out of anesthesia 9.30 P.M.

9.35 P.M., temperature (rectal), 38°; 10.15 P.M., 37°; 11.15 P.M., 37°

Shock symptoms approached gradually with the usual inactivity and weakness.

Following morning the rectal temperature at 5 A.M. was 36.5° C.; 9 A.M., 36.5°; 12 A.M., 36°; 12 P.M., 35°.

Animal very weak. Chronic shock symptoms, apathy sensations, and reflexes nearly abolished with great disability. Heart beats weak, respirations shallow, general pallor and coldness.

Second Twenty-four Hour Period.—8 A.M., temperature, 34.5°; 6.30 P.M., 34°. Shock symptoms complete. 8 P.M., animal died.

Post-mortem Examination.—Liver, stomach, upper part of small intestines show the usual shock picture of congestion and edema, with pallor of the lower splanchnic area. See histological findings, Figs. 9, 10, 11, 12, and 13.

Experimental Shock Produced by Burns.

EXPERIMENT VIII.—*Rabbit No. 1.* Burned over the back (under anesthesia). The burned area was removed and grafted on the back of rabbit No. 2. The normal skin removed from rabbit No. 2 was transplanted on the back of rabbit No. 1 in the burned area where the burned skin had been removed. *Result:* Shock symptoms developed in rabbit No. 2, receiving the burned skin transplant, and died in sixty-eight hours after presenting the symptoms and pathology of shock. The original rabbit No. 1, receiving the burn, recovered with but slight shock symptoms.

Ten grams of the burned skin was ground up, to which was added 10 c.c. sterile water, placed in incubator with antiseptic to inhibit bacterial growth. Eight c.c. of this burned skin emulsion was injected into rabbit No. 3. The shock was immediate, with staring coat, nystagnus, respiratory and circulatory failure. Death occurred in five hours.

EXPERIMENT IX.—*Cat No. 1.* Burned along the back spinal region. Light burn. Skin dissected transplanted to cat No. 2. The symptoms did not occur for four days. Absorption was delayed. Post-mortem examination revealed the usual findings of shock.

Injection of 2 c.c. of a 1 to 10 autolyzed emulsion of skin into cat No. 3 caused immediate shock symptoms, staring coat, nystagnus, contracted pupil, followed by great apathy; finally recovered.

In all the burned skin experiments it was clearly evident that the degree of shock depended upon the degree of burn and the extent of the skin trans-

plant. It was also found that the degree of shock was directly proportional to the dosage of the autolyzed cells.

Shell Shock Experiments.

EXPERIMENT X.—8.15 A.M. Guinea-pig 1 was

FIG. 1.—Low Power. Near pylorus; venous stasis in the submucous tissues, showing venules entirely empty, the plasma and corpuscles having diffused out into the perivascular tissues.

wrapped in a small cloth bag, bound to a small stand, and placed close to a centrifuge revolving 10,000 revolutions per minute. The projecting arm was to imitate a passing shell without touching the animal. Time in the chamber was thirty seconds.

Animal showed marked effect at once, observed for ten minutes, and replaced in the centrifuge chamber another thirty seconds. Removed the animal and found

FIG. 2.—High Power. The plasma is shown diffused into the perivascular tissue, pushing it away from the vessel; the blood cells have extravasated and some of the corpuscles can be seen in the act of passing through the wall.

that, although blindfolded, it suffered high degree of shock symptoms; eyes dull, fur staring.

8.45 A.M.—Temperature, 35° C.

8.50 A.M.—Trembling was extreme.

1.05 P.M.—Temperature 36° C.

3.45 P.M.—Animal was in crazed condition, watched under a glass bell jar, began to eat feces, and chewed frantically at steel forceps under the jar.

Post-mortem 6 P.M.—Upper part of the intestines and stomach were markedly congested with hemorrhages. Liver showed extensive small hemorrhage areas. Kid-

FIG. 3.—Cat 1. From the pylorus; submucous venous congestion showing corpuscular agglutination.

ney and spleen were also hemorrhagic. Brain and spinal cord findings were practically negative, except that the membranes were congested. Medulla normal. Heart normal. Calculations of the area of the small hemorrhages evident throughout the body showed that it represented a greater degree of trauma than that produced by the thigh muscle injuries in the other experiments.

EXPERIMENT XI.—Guinea-Pig 2. Weight, 775 grams. Placed in centrifugal chamber thirty seconds. Repeated after five minutes. Fall in temperature as in previous experiments, with gradual recovery.

Ten days after the experimental "shell shock":

FIG. 4.—Cat 1. "Clumping" in the portal veins and marked distention of the intercellular portal capillaries; the periportal changes in the parenchyma are well marked.

Weight, 649 grams. Loss of weight, 120 grams. Kept under same food as before and with other animals. Coat rough and dull. Animal dull and listless, as compared with other animals.

Fifteen days after first "shell shock": Weight, 620

grams. Total loss, 155 grams. Continued on same food as before. Animal again placed in centrifuge thirty seconds. Animal in deep shock.

Post-mortem.—General findings of ordinary traumatic shock. Brain and spinal cord negative. (Fig.

the four important detoxicating and eliminating organs—liver, stomach, upper intestines, and lungs, show the brunt of the reaction. The kidney shows the later manifestations.

FIG. 5.—Rabbit 5. Autolyzing muscle tissue taken from the wounded area in the leg.

27.) Animal pregnant. Small embryo shows similar viscereal hemolysis, but brain and spinal cord are intact. (See Fig. 28.)

EXPERIMENT XII.—Guinea-pig No. 3. Weight, 760 grams. Shock in centrifuge. In chamber thirty seconds. Followed by usual shock symptoms, with fall in temperature.

Following day, weight 722 grams, and thereafter there was a gradual loss in weight.

For "shell shock" histological findings, see Figs. 24, 25, 26, 27, and 28.

These experiments are illustrations of hundreds of like experiments observed by the writer and are

FIG. 7.—Rabbit 5. Liver; portal congestion and extravasation of blood and plasma. Periportal area shows autolytic changes.

When the reaction takes place as an acute condition it is seen to be vascular in character; later and in its more delayed condition the cellular elements take a decidedly primary part in the reaction termed shock.

In the liver we see the first changes in the vessels. In the stomach and intestines the first area involved is the submucous tissue, the "zona transformans." The endothelial lining of the pulmonary artery shows an early reaction. The cells that take part and seem involved at once are the endothe-

FIG. 6.—Rabbit 5. Section of stomach; blood escaping from vessels, passing with the serum into the surrounding submucous tissue.

to be interpreted by drawing a strict distinction between the primary conditions of shock and the secondary effects which follow. In all the experiments it is repeatedly seen, in both acute and immediate shock as well as in the more delayed process, that

FIG. 8.—Retina.

lial cells of the small vessels; later the parenchyma of the organ is involved.

The injured tissue soon seems to undergo autolysis and absorption products form; these are carried into the system and must be disposed of. The elimi-

nating and detoxicating organs are the stomach and upper intestines, the liver, lungs, etc., in which the reaction which takes place is first seen.

The injuries in "shell shock" and those caused by

died from acute shock, immediate post-mortem examination and fixation of the tissues showed the final results, comparing well with the progress of shock as studied in various stages.

FIG. 9.—Cat 5. Stomach, pylorus: submucous tissue (zona transformans), showing marked venous engorgement with extravasated cells.

sudden positive and negative pressure are molecular in character and this causes the colloidal dispersion of the cells and fluids similar to what is obtained by the action of a toxin.

There is no evidence that the nervous system plays a role in shock. Whatever manifestations are there apparent are secondary.

General Pathology of Shock.—Many of the specimens shown in the accompanying illustrations were obtained from the tissues before death, before any change had occurred except the primary phenomena

FIG. 11.—Cat 5. Lung: blood "clumped" in the vessels with peripulmonary arterial congestion.

The specimens shown in Figs. 1 and 2 were taken from an animal before death and placed in a fixing agent, and although this experimental work was done in 1893, it is so characteristic of shock, that the specimen is again shown with both high and low power. This was taken from a series of experiments which were published, and in which the author concluded that the shock was due to a toxin of the nature of "self-formed peptone."

Since that time the experiments have been continued and indicate that whatever form of injury induces shock, the result is the same. This is not

FIG. 10.—Cat 5. Liver—portal zone; active venous stasis with periportal extravasation.

of shock. Small sections were immediately fixed in formalin or Zenker's solution; other fixing agents were used for special stains. For general purposes hematoxylin and eosin were used. Where the animal

FIG. 12.—Cat 5. Kidney, low power; straight tubular venous stasis with "clumping" of the corpuscles.

surprising when we consider the colloidal character of the tissue, which follows the laws governing all colloids. The living tissue is the arena of colloidal catalysis and adsorption phenomena.

An apparently small exciting condition may precipitate the entire colloidal system. This T. Graham first showed in 1861.^{13a}

The colloidal dispersion changes in shock are in-

disaster has brought about all the changes in general pathology and we must include also the special pathological changes found in shock.

The "shell shock" animals show most interesting

FIG. 13.—Cat 5. Kidney, high power; glomerular region, showing hemorrhagic areas with agglutination of the sera and corpuscles.

indicated in every phase. First the injury, when peptization occurs soon after the lesion, the products of which are carried by vascular and diffusion routes into the organism, where the "mutual precipitation of two oppositely charged colloids" results in the fulminating reaction we call shock.

All the variations in viscosity have already been noted by many experimental observers in the study of shock, though rarely so interpreting their findings.

When the intense reaction is seen in the splan-

FIG. 14.—Cat 6. Stomach, pylorus; congestion of the submucous tissue (zona transformans).

nic area in acute shock, and also the emptied vessels with edema of the tissues, the falling temperature, blood pressure, and final bankruptcy of metabolism, we must conclude that a profound colloidal

FIG. 15.—Cat 6. Duodenum congestion descending from the submucous tissue into the mucosa.

colloidal disturbances brought about by the positive-negative air pressure, accomplished by placing the animal one inch away from a single arm projecting from a centrifuge at high speed (revolutions 12,000 to 15,000 per minute).

All the viscera except the brain and spinal cord show marked congestion and hemorrhages. The embryo is not spared in this action except the brain and spinal cord which seem well protected against "air pressure," blows with an instrument, or other like physical injuries. Rabbit 3, Experiment No. 4, also shows the fulminating acute reaction caused by

FIG. 16.—Liver; characteristic deformation in portal veins with the usual periportal changes.

injecting the "shock toxin" (autolyzed injured muscle emulsion) into the mesenteric vessels—intense gastric and duodenal submucosal congestion and hemorrhage. (Figs. 18 and 19; marked portal re-

action noted in Fig. 20). The value of this experiment is that the tissue was taken and fixed while the phenomenon was observed *intra vitam*.

Rabbit 6 shows the effects of immunizing doses

the body, except the brain and spinal cord. Skeletal muscles also escape to a great extent.

Hemorrhagic areas may appear in the membrane of the brain and spinal cord as a secondary phe-

FIG. 17.—Cat 6. Brain; shows no congestion and the cells appear normal, as is always the case in primary shock.

of the autolyzed muscle tissue. Two sublethal doses were intravenously injected and after the second dose the animal was opened and tissue removed for histological study. The liver, Fig. 23, shows the reaction similar to that found in fatal shock, though less severe in the degree of the portal and periportal reaction. The venous stasis in the submucosa of the pyloric region (zona transformans) gives the same picture of primary reaction as in fatal shock. When immunity is well established

FIG. 19.—Rabbit 3. Duodenum; submucous congestion.

nomenon. The aggregate lesions in these "shell shock" animals throughout the body amount to more "wound injury" than may occur from a lacerated wound of the thigh. In Figs. 24 to 28 the character and extent of the injuries are well shown. The same autolysis from these smaller multiple wounds seems to account for the chronic character of the symptom often observed in these experimental animals. They show also a gradual loss in weight up to the time of death, which varies according to the degree of injury and other factors.

Special Pathology.—In experiment Rabbit 5, Fig.

FIG. 18.—Rabbit 3. Stomach; high power; intense congestion and hemorrhage; the "acute" colloidal reaction is shown in the fulminating result of mesenteric injection of the "shock toxin" in producing its first effect in the zona transformans extending into the mucosa.

these reactions do not appear except in a very slight degree.

The experimental shell shock animals show a wide extent of diffused hemorrhagic areas throughout

FIG. 20. Rabbit 3. Liver; shows the portal and periportal reaction of acute shock.

5, is shown some autolyzing muscle tissue in the early stage of autolysis, plasmolysis, and nuclear changes, fading out stain reactions (hematoxylin and eosin).

The effect of absorption of the autolyzed muscle is shown in Fig. 6 by the extensive hemorrhagic congestion in the submucous tissue of the stomach wall (zona transformans).

zone; hemorrhagic congestion of kidney is shown in Figs. 12 and 13—low and high power.

In Cat 6 (experiment in acute shock), injection into the jugular vein of autolyzed muscle tissue

FIG. 21.—Rabbit 6. Shortly after the second intravenous immunizing dose of "shock toxin," pylorus submucosa shows the venous shock reaction as a "zona transformans colloidal reaction."

Fig. 7 shows the portal congestion of the liver which indicates active reaction.

Absorption reaction of shock is well shown in experiment No. 1, Cat 1, Fig. 3, pyloric submucosal congestion (zona transformans), and Fig. 4, active portal congestion of the liver.

In experiment 5, the mucous tissue from a flesh wound of a cat in shock was inlaid or transplanted

FIG. 23.—Rabbit 6. Liver; the portal zone reaction of shock phenomena and "clumping" well marked.

from an homologous animal in shock, caused death within three minutes.

In the stomach, Fig. 14, and duodenum, Fig. 15, the classical pathological picture of shock with marked congestion in all "detoxicating zones," of the viscera is well shown in the microphotographs. The brain, Fig. 17, is normal as is also shown in a more prolonged shock status.

Fig. 29 represents diagrammatically the phenomena leading up to and associated with shock.

FIG. 22.—Rabbit 6. Intestine; mild shock reaction, no marked extravasation.

into the leg of Cat 5. The absorption from this caused death from shock.

Fig. 9 shows stomach submucosal congestion. Fig. 10 portal congestion of the liver. Fig. 11 intense lung congestion in the pulmonary arterial

FIG. 24.—Guinea Pig 10. Shell shock experiments; submucous congestion.

Treatment.—Shocks produced by wounds, burns, exposure, handling of the viscera, artificial "shell shock," etc., all seem to result in one and the same condition, namely, rapid autolysis of the injured

cells, the products of such autolysis causing the classical syndrome of shock and death.

Repeated small injections of these autolyzed tissue cells or of their products result in such a high

writer has previously published experiments showing that the production of immunity to shock may be facilitated by the application of heat which influences the circulation in the splanchnic area. The

FIG. 25.—Guinea Pig 10 (shell shock). Liver; congesting portal veins with hemorrhagic streaks radiating from the portal zone.

degree of immunity that one hundred times the fatal dose can be injected without producing symptoms. Furthermore it has been shown that immunized animals are refractory to the usual procedures that induce shock.

Still another interesting fact revealed is that in immunized animals wounds heal more readily and seem less susceptible to infection.

These observations naturally lead up to the question of the possibility of the production of immunity

FIG. 27.—Guinea Pig 10 (Shell shock). Brain; shows no congestion and cells appear normal, as is seen throughout the nervous system in primary shock.

application of heat to be effective must be made as promptly as possible after an accident likely to produce shock and must be continuous. The attachment of an electrical heating device with a small storage battery to each stretcher on the battlefield would prove to be a practical and life-saving measure.

In 1896¹¹ the author showed the analogy of pro-

FIG. 26.—Guinea Pig 10 (Shell shock). Lung; marked hemorrhage; congestion; the mechanical action of positive-negative air pressure on the body sometimes has more effect in the lung than any other viscera.

to shock in the human. Experiments bearing on this point have been conducted and will be presented in the near future.

In the meantime it may be recalled that the

FIG. 28.—Guinea Pig 10 (Shell shock). Embryo; section through body from Guinea Pig 10 in "experimental shell shock" shows marked congestion with small hemorrhages throughout all the visceral area except the brain and spinal cord; the cord is well shown without congestion or hemorrhages either in the membranes or tissue.

teous intoxication and shock symptoms and that these were akin to snake poisoning.¹² In the case of snake poisoning the most effectual method of treatment is to tie up the leg or poisoned area, and re-

move the tissue; later injections and other methods of producing immunity are to be used. In the treatment of wound shock we may carry out the analogy. This may be done by the prompt application of

FIG. 29.—Graphic summary of the phenomena of shock.

strong antiseptic and astringents (such as formalin 15 per cent. and bichromate of potassium) to stop the absorption of the toxins and prevent bacterial growth,* and the administration of non-toxic and antiautolytic substances according to the indications. The prophylactic measures of the elastic ligature and of removing all autolyzing tissue that endangers the victim (débridement), are generally acknowledged to be the first indication in wound treatment. A full report on methods of treatment will soon be published with the experiments and findings in the production of immunity.

BROKEN NOSES, THEIR PATHOLOGY AND TREATMENT.

By WILLIAM WESLEY CARTER, A.M., M.D., F.A.C.S.

NEW YORK.

IN view of the importance of the nose, from both a cosmetic and functional point of view, one would

disregarded the laws of mechanics. The mistakes were made at the time of the injury, the very time when the application of the correct mechanical principles could have secured the best results; in many cases perfect results, for it is possible by the use of a properly constructed mechanical appliance to bring the fractured and displaced parts back into

FIG. 1.—Before operation.

FIG. 3.—After operation.

think that the treatment of traumatic injuries of this organ would long since have been standardized, and placed upon a scientific basis; but such is not

their normal position and hold them there until union has occurred.

The nose is an equilateral arch, and must be re-

FIG. 2.—Before operation.

FIG. 4.—After operation.

the case. Sufficient evidence to support this criticism is presented by the great numbers of deformed and obstructed noses that come under our observation, due, the majority of them, to the application at the time of the injury of treatment that totally

garded as such from the architectural, mechanical, and surgical point of view. This arch must be considered as being made up of an indefinite number of segments assembled in a curved line in such a manner as to retain their position when the struc-

ture is supported extraneously only at its two extremities. The thrust of an arch is the pressure which it exerts outward, and this pressure is usually collected, so far as it exists as an active force, at a point about one-third of the height of the rise of the arch. In the nasal arch this point is not far from the suture between the nasal bones and the nasal processes of the superior maxillæ. When a heavy blow falls upon the nasal bridge these are the points which must bear the brunt of the force, and consequently where the breaking of the arch occurs. On account of the resiliency of the soft tissues and the swelling which follows the injury, the damage to the arch at these points may not be noticeable, but we may be sure that it is there if the blow has been sufficient to fracture the nose. We may also be reasonably certain that if the parts of the arch are not brought into their proper position before the healing has occurred, and cicatricial contraction has still further displaced the fragments, there will result an irregularly deformed nose with a flattened bridge, and, what is still more important, more or less complete obstruction to nasal breathing, due to the crumpling up of the septum and the depression of the bridge. The septum as a vertical support cannot be considered necessary to the maintenance of the integrity of the nasal arch, though it does strengthen it, and no doubt does, in many instances, limit the damage done by the traumatism. The importance, however, of the upper edge of the cartilaginous septum, where it fits in between the two lateral cartilages and forms the keystone of the arch, cannot be overestimated. I have referred to this on several occasions, and have demonstrated a number of cases of depressed nasal deformity due to the dislodgement of this important segment of the arch by operators who used tugging instruments for the removal of the cartilaginous septum in doing the submucous operation. Deformities resulting from this accident can be corrected only by the transplantation of bone or cartilage from some other part of the body to take the place of the segment destroyed. The destruction of this segment in septal abscesses and when infection occurs after the submucous operation always results in a flattened nose. In doing the submucous operation I have always advocated the use of a punch-forceps in removing the septum, for I believe that this instrument safeguards the position of the septal segment of the arch better than any other. I am still using, with great satisfaction, my original punch-forceps—the first forceps devised for this purpose—and I have not yet had one of my submucous operative cases subsequently develop a deformity.

All fractures of the nose are compound, the communication with the air being through the mucous membrane, though the skin is frequently torn through as well. In the latter case, especially, great care should be exercised to prevent infection. If this can be accomplished we may be sure that practically all of the bones and mutilated soft parts will be saved, for on account of the great vascularity and wonderful resistance to infection, especially to the bacteria usually found in the nose, compound fractures are seldom attended by the serious consequences which sometimes follow similar injuries in other parts of the body.

In order to reconstruct an arch which has been destroyed either by the fracture or the dislocation of some of its segments, the logical and practical expedient is to apply force in a direction diametrically opposed to that of the force which caused the injury. This is exactly what is done when the bridge splint, an instrument which I devised several years ago, is properly applied. If the fracture is a recent one, or if the patient is not seen immediately after the injury and the swelling has subsided, the segments of the arch can usually be brought into normal alignment by the application of the instrument alone. Sometimes, however, where there has been unusual displacement, or where blood clots have begun to organize between the fragments, the Adams forceps should be used to adjust the fragments before applying the instrument.

The literal, unmodified application of the principles of the arch to fractures of the nose can be made only in the case of recent fractures, for in the case of old, traumatic deformities the scar-tissue present, which is always considerable, has thoroughly bound together the broken fragments in their false position, and by its contraction has increased the deformity. In addition to this the cartilaginous septum is usually so thick and massive that nasal respiration is greatly impeded, or it may be completely obstructed on one or both sides. I have seen the septum split into two distinct layers of cartilage. As a rule, however, the thick septum in these cases is due to a crumpling up of the cartilage. Between the broken fragments dense bands of connective tissue pass through from side to side, binding together the two layers of the mucous membrane. In the case of such a septum as this, of course, the cartilaginous bridge of the nose is held down by the septum, and cannot be raised until liberated from this anchorage. Formerly I have advised making a diagonal incision through the septum from the floor of one nostril to the roof of the opposite nostril, thus permitting the bridge to be raised, the upper and lower halves of the septum sliding by each other to a certain extent. When the bridge was raised the septum was thus lengthened without leaving a perforation. Cases in which I have done this operation have not held up as well as I expected, nor was the relief from the nasal obstruction sufficient. I have therefore abandoned this procedure, and instead now perform a submucous operation, leaving a fair amount of cartilage along the upper margin of the septum to reinforce the bridge, which I construct by transplanting bone after the recovery of the patient from the submucous operation and the bridge-splint operation, which are done at one sitting. In applying the bridge splint in these cases it is absolutely necessary to mobilize completely the broken parts of the nasal arch, and in addition to this to remove all of the scar tissue that is accessible and utilize the nasal processes of the superior maxillæ, which are chiseled off from their attachment by means of a special chisel applied from within the nose. The dorsum of the nose is then easily raised to a normal position by means of the bridge splint, which holds it in position for about two weeks. At the end of this time the nose has apparently been perfectly restored, and it has been, but not permanently, as experience has now shown me. The contraction

of the large amount of scar tissue, which is invariably present in such a nose, depresses the bridge, and within a few months the deformity is as bad as ever. I now prevent the return of the original deformity by transplanting bone and cartilage from the rib immediately after the patient has recovered from the bridge splint and submucous operation. The splendid restoration of the nose effected by the bridge splint is thus made permanent by the support of the transplanted bone.

The results I have secured by this combined, two-stage operation have been excellent, and I am quite sure that they are permanent, as a sufficient time has elapsed to show. All of the work is done from within the nose and no operative scar results.

An extensive experience in this work convinces me that the rib is best suited for transplantation into the nose. In those cases where there is also a drooping of the tip, and it is necessary to extend the supporting transplant nearly to the end of the nose, I take my transplant from the rib where it joins the costal cartilage; the upper two-thirds is composed of bone and the lower third of cartilage. The normal structure of the nasal bridge is thus restored and the flexibility of the tip is unimpaired.

I have cases of over ten years' standing, and the results remain as good as they were at the time of operation. The transplant I always anchor securely to the frontal bone, with which it soon forms an osteogenetic connection. If this connection is properly effected the transplant is not absorbed, but it lives and grows, its growth being limited by the functional demands of the part.

The procedures here advocated for the treatment of traumatic nasal deformities and obstructions have been thoroughly tested by me in a large number of cases; there have been no serious accidents and the patients have been relieved. I regard the method as safe and efficient and the results secured as permanent.

69 WEST FIFTIETH STREET.

THE CARREL-DAKIN TREATMENT—ITS APPLICATION IN SURGERY IN CIVIL PRACTICE.*

By MARTIN W. WARE, M.D., F.A.C.S.,

NEW YORK.

(From the Surgical Service of Mount Sinai Hospital, of Dr. H. Lillenthal)

I ASSUME for this audience a familiarity with the Carrel-Dakin method gained from print or lecture given by the chief exponents thereof. These representations, however, have mainly concerned themselves with its application to the vast wounds of war surgery. The question is therefore proper how far this method is applicable to the infected wounds encountered in civil practice.

Critics have decried its use because of the apparent finesse demanded in its execution. But this opposition was alike encountered by Listerian antiseptics and asepsis evolved from it. The practice of either called for a technique, or rather the appreciation of a principle. Listerism meant the destruction of all germs by the medium of carbolic acid pervading the atmosphere, permeating the

dressings, penetrating the surfaces and recesses of the wound, and bathing all of the armamentaria, in addition to the observance of the already well-understood mechanical principles of wound treatment, whereas asepsis implied the same destruction of germs without the aid of chemicals.

In the course of time asepsis grew to be a nigh universally accepted practice of surgeons and physicians in the treatment of all non-accidentally inflicted wounds from the minutest puncture of the hypodermic needle up to the performance of the most capital operation. But when it came to the treatment of accidentally inflicted wounds *eo ipso* infected, whatever the grade and extent of infection, there was the greatest diversity in the plan of treatment. The Carrel-Dakin method offers for the first time, it appears to us, a precision applicable to infected wounds.

Carrel-Dakin is not necessarily a vindication of antiseptics, but rather a combination of the latter with asepsis. Rigid asepsis is a *sine qua non* in order to promote the efficiency of the antiseptic employed by Carrel, but very often the mechanical feature of time honored drainage with gauze or tube irrigation of the wound, or opening of the infected area at the dependent point, has been wholly dispensed with. Carrel-Dakin is not a method of irrigation or drainage or wet dressing. By intermittent instillation of small quantities of the hypochlorite solution, at intervals of two hours, a gradual sterilization of the infected terrain *in loco* is aimed at. By such sterilization and reduction of bacteria, secretion is reduced, and drainage either with tubes or gauze is not called for. The agents employed by Carrel must be intimately brought in contact with the wound and retained there for a sufficient time to accomplish the purpose. Therefore, in the first instance, any wound made by the surgeon should not be placed at a dependent point as heretofore, but rather so as to enable the fluid to lake and form a pool.

The mechanical means to accomplish this calls for the armamentarium devised by Carrel. They are the tubes of 4 mm. diameter, closed at one end by a ligature of linen thread, with minute perforations extending over a variable length according to the depth of the wound. Another variety of tube employed is that covered over with turkish toweling. These latter tubes from their resemblance to ramrods, I would designate as such. The perforated tubes never extending beyond the surface of the skin are led to the bottom of all the recesses of an irregular wound. For a surface wound, one such tube in the form of a loop with perforations on the inside, so that the spray of fluid will spread out over the surface or a number of such tubes placed parallel or a ramrod tube will suffice. The use of any gauze in the wound separating the walls thereof is unnecessary; only such gauze to prevent the tubes from being displaced should be placed at the orifice of the wound.

Dr. Louis, a collaborator of Carrel, warns against the use of ramrod tubes, since they are prone to be blocked with the secretion and thus become ineffective for the escape of the disinfecting fluid, and for this reason inclines to a freer use of the perforated tubes, in larger number with larger perforations when the wound is of the surface variety. It may also be necessary to tie the tubes in place

*Read before the Metropolitan Medical Society, New York, Feb. 25, 1918.

with the aid of a linen string, long enough to pass about the member, or to have each end held securely to the skin with zinc oxide plaster. When all the tubes are in place it should be aimed to have their orifices point in one and the same direction, so that they may be coupled up with the supply tube of larger diameter attached to the reservoir, from which the chlorite solution is delivered. A further nicety is called for in coupling up the adjustment so that each tube obtains the same amount of fluid at the same time. This is attained by using glass couplings with three or more nipples. When the Carrel irrigating bottle is used it is necessary to adjust the regulating pinch-cock so that with the release of the main pinch-cock a definite instillation and no flooding of the wound will follow. The skin everywhere about the wound has to be protected from the corroding effect of the escaping solution, by covering the skin with squares of gauze impregnated with vaseline. Immediately overlying the wound a compress of gauze is placed, which by its weight holds the tubes *in situ* and takes up the solution. For wounds of the extremities the whole part is enveloped in a gauze-cotton quilt, the edges of which are held securely with the aid of clothes-pins or safety-pins. This latter arrangement is at once economical as well as permitting instant and rapid examination of the parts. The limit of the efficacy of the hypochlorite solution in time is reached in two hours, wherefore at such intervals the pinch-cock is released to instill more fluid. The use of the Carrel-Dakin reservoir and the mechanism of the pinch-cocks is of service in a hospital where a large number of patients are under treatment, but in private practice of isolated cases the estimated quantity of fluid, averaging 10 c.c., can be injected with the aid of a small-sized catheter-tipped glass syringe. On the other hand, an automatic device with a water trap siphonage* enables one to dispense with a nurse. Each second or third day a cover glass preparation of the secretion is microscopied to ascertain the number of bacteria to several fields, and when on two or three successive days the minimum of three has been reached, the wound edges may be adapted by strips of adhesive plaster without dependence on any further drainage, or if it be a surface wound, the same is ready for grafting.

The Carrel-Dakin method in orthodox fashion has within the past year been introduced by Dr. Lilienthal on his service, and step for step its application has been extended to every appreciable condition of infected wound. I believe I can best bring home to you its possibilities by illustrative cases:

CASE I.—The first trial concerned a child whose empyema was discharging a profuse blue green pus caused by bac. pyocyan. This infection as usual so refractory to most measures, completely vanished after 36 hours, the wound assuming a healthy granulating appearance and within a short time thereafter healing was complete.

CASE II.—An extensive palmar cellulitis had been subjected to free incision and drainage with superimposed wet dressings. The infection none the less spread to the articulation of the thumb so disintegrating the bony joint surfaces that amputation followed. Even then the wound surface, in spite of usual antiseptic

tive treatment, was coated with a profuse purulent discharge and necrotic granulations for a period of two weeks. Forty-eight hours after beginning the Carrel-Dakin irrigation, the secretion markedly diminished, the wound began to assume a healthy granulating appearance and within another ten days complete cicatrization had set in.

CASE III.—A cellulitis of the forearm had progressed so far in an aged female—a diabetic—that I amputated at the elbow. The resulting wound conditions were anything but favorable; fascial necrosis and pus continued to issue from this wide open wound, in the face of any treatment. After the use of the Carrel-Dakin treatment a marked change set in; within a week the granulations were firm and bright red, and the bacterial count having been reduced to a minimum, the wound permitted being strapped. Within another ten days the exposed cartilage of the humerus which had threatened to necrose, became covered with healthy granulations and healing was completed in two weeks.

A most frequent group of cases subject to a long period of suppuration are the wounds incident to drainage of suppurative appendicitis. If we institute the Carrel-Dakin treatment on the fifth or sixth day when adhesions have with certainty circumscribed the suppurating area from the general cavity within three or four days the secretion markedly diminishes; it loses its offensive odor, the bacterial count fails and very often within another week healing is complete. Thus it has repeatedly happened that the extensive purulent appendicitis case will be discharged within the same limit of time as the case which was completely closed at the operation.

A like experience may be encountered when the Carrel-Dakin system is applied to the empyema suppurating cavity. Here as many as three or four tubes are employed. On three occasions extensive suppurating cavities have been so quickly freed of the suppuration and its accompanying fetid character that the wound could with impunity be strapped at the end of 10 to 14 days, and by the third week the patient discharged.

If after the first change of dressing of an osteomyelitis wound, when all the hemorrhage has ceased, the Carrel-Dakin irrigation is applied, the granulations rapidly assume a bright red color and quickly reach the level of the skin surface, so that the edges may be strapped within two weeks or the surface grafted. Two such cases which had been treated with iodoform bone wax did not go on to primary union, notwithstanding the exacting technique employed, but removal of the wax and Carrel-Dakin application brought about a rapid change.

Extensive wounds following burns may be brought into the most favorable condition within a much shorter period of time for skin grafting than by any of the previous methods, all of which were painful because of gauze used.

Suppurative mastitides, with one incision substituted for the older practice of multiple incisions, have been completely healed within two weeks.

The misapplication of the Carrel-Dakin treatment was gained from its use in an extensive gangrene of the skin of the whole thigh following contusion. To the denuded suppurating surfaces irrigation was applied awaiting the separation of the slough. Herein consisted the error, for while the wounded surface areas took on a healthy appearance, and the bacteria count subsided, erysipelas set in. The mistake was committed of not removing at once the necrotic area and so creating a wound surface,

*See Dr. Howard Lilienthal in the *Military Surgeon*, XLII, No. 2, February, 1918, p. 258.

every part of which could be reached by the Carrel-Dakin solution.

Innumerable instances could be multiplied that would bespeak an efficacy of the Carrel-Dakin treatment for infected wounds far beyond what has been accomplished by the drainage with or without the use of antiseptics and in much shorter time.

This does not imply that every accidental and infected wound should be treated by the Carrel-Dakin method. The indication for its prompt application will depend on the initial count of the number of bacteria in the field. Where these are scant, our present-day methods may suffice to do as well with less effort. But at the first sign of delay in healing the Carrel-Dakin method should be instituted.

The Carrel-Dakin solution is a properly assayed hypochlorite of calcium, of the strength of $\frac{1}{2}$ per cent. Its proper preparation has been a matter of much controversy. It can be obtained commercially from various concerns. The preparation of chlorazene dissolved in aqueous solutions 1 per cent. suffices.

The use of a chlorine compound, such as chloramine-T, incorporated with a neutral base so as to make it available for an ointment was welcomed because it was regarded as being a short cut in the treatment in lieu of Carrel-Dakin solutions. But this preparation of the solution with stearate of soda is difficult to make in small quantity and does not answer since it fast loses its chlorine. Hence the caution not to rely on the commercial product, if you can in any way be favored by a fresh preparation prepared by a chemist.

27 EAST 81ST STREET.

SOME RECENT STUDIES IN PERCUSSION AND AUSCULTATION IN PULMONARY TUBERCULOSIS.

BY MAX GROSSMAN, M.D.,

BROOKLYN, NEW YORK.

THE diagnosis of what constitutes so-called early pulmonary tuberculosis is in more or less confusion to-day. Different clinicians have expressed opposite views concerning the subject. Some men hold to the view that symptoms should be the main factor to be considered. Others, equally positive, say that physical signs, if properly elicited, are good enough guides in coming to a decision. No one can deny a diagnosis of pulmonary tuberculosis when the sputum shows the presence of tubercle bacilli. But there are many cases, even when the tuberculosis is advanced, in which the sputum is for a time negative. It is therefore necessary in coming to some definite conclusion in the matter, that a happy medium should be expressed. While symptoms, if obtained, should never be ignored, yet their absence for a time, and although the history of the case is negative, should not preclude the possibility of existence of early pulmonary tuberculosis.

The study of physical signs in pulmonary tuberculosis has always been of special interest for life insurance examiners, since with them at times, the applicant will mislead, and they must employ physical signs when possible, and so pass upon the risk and the rating. Moreover it would seem that a discussion of the subject at present might be of value, since we are at war, and medical boards are occa-

sionally examining applicants whose words concerning their health are not reliable; loss of weight, general debility, cough, even afternoon temperature and night sweats are relative terms, and do not always spell pulmonary tuberculosis. Some men in seeking to avoid being drafted, will give a history which has been carefully studied, and in which the symptoms would point to pulmonary tuberculosis, but still these same men have sputum free bacilli, and entire absence of physical signs.

It has seemed to the writer, accordingly, that it is of great importance to-day to take up the subject of diagnosis of pulmonary tuberculosis, and to emphasize such worthy points, if he is permitted to use that term, as have come up in his humble experience.

Of the different methods employed, inspection, palpation, percussion, and auscultation, it would appear that the most advances in their comprehension in recent years have been along the lines of percussion and auscultation. Percussion, if properly studied, is not so difficult a problem to handle, and almost every one with moderate study and application can acquire enough knowledge for daily use.

The different types of percussion notes generally stated in text books are the vesicular, dull, and flat; some authorities add amphoric and tympanitic. There is a note, however, which is as yet not sufficiently known and understood, and that note is the dull-flat. It was described some years ago and its further study and application should be of benefit in helping to unravel the mysteries of the human adult chest.

Dr. Robert Abrahams, the originator of said note at the time, wrote as follows (*Archives of Diagnosis*, July, 1910): "Technically the dull-flat note is shorter in duration and higher in pitch, its acoustic qualities stand between dullness and flatness, or it is a note which is duller than dull. Now as to its diagnostic value in incipient tuberculosis. But first, I wish to emphasize the strangely misunderstood fact that some areas of the lungs normally possess dullness on percussion. Now in the presence of an early infiltration either of these areas drops its normal dullness and assumes the dull-flat resonance. This change in tone is unmistakable on light percussion. Hand in hand with the modification in resonance there will be found a corresponding proportionate change in the resistance. The dull-flat note is also of value in ascertaining the progress of the tuberculous process in any part of the lung. Take, for example, the left apex. Under normal conditions the percussion note of the left apex is pulmonary or vesicular. In the presence of an infiltration the vesicular resonance will change into dullness; dullness indicates incipency. By watching the modifying degress of the dullness in that apex and the eventual change of that note into the dull-flat, one can predict with accuracy the progress that the tuberculosis deposit is making."

It can be easily seen, therefore, that in taking the right apex for instance, the term dull-flat is really a key to the whole problem. From dullness, the normal percussion note at that apex, to flatness, the note of advanced tuberculosis, expresses the change in percussion which takes place in pulmonary tuberculosis. The change is not as a rule an acute one, and the intermediate type is the dull-flat note, since pulmonary tuberculosis generally is

a chronic process and the note does not change from dullness to flatness over night, but often takes years for its accomplishment.

In studying the left apex we find vesicular resonance as a normal proposition, but when this apex is the seat of tuberculosis the note changes to dullness and after that goes through the same changes as described for the right apex. In coming to the apices of the lungs posteriorly, the writer takes the liberty to designate the same as having a dull-flat note as a physiological condition, and by the use of the term in this manner believes the subject is much simplified. Certain it is that the textbooks are as yet strangely silent on this point. There is much difficulty in making a diagnosis of pulmonary tuberculosis, employing percussion alone and attempting to do so by studying the changes of percussion note and applying the same posteriorly to the pulmonary apices.

Anteriorly percussion over the clavicles will help at times in the diagnosis. If a process is located in back of that bone, the percussion note will change; at the right apex becoming dull-flat; at the left apex becoming dull, then dull-flat; and finally either or both become flat in character.

The writer in this article will describe a new type of respiratory murmur which occurs abnormally and for which he takes the liberty to create a new name, to wit: semibronchial breathing.

The term dull-flat, applied by Abrahams, designated as none had done before, the percussion changes of the right apex in the advance from incipency to advanced pulmonary tuberculosis. But now, how about the changes in the respiratory murmur? There are certain changes taking place, for example at the right apex, in the change from normal bronchovesicular breathing to the bronchial type. The change here, as a rule, is not acute, and very often takes many years; the intermediate type, it seems to the writer, is a distinct type of respiratory murmur, worthy so to be classified and called. By appreciating the term, semibronchial breathing, one is able to unravel a pathological process which would otherwise remain more or less a mystery. The semibronchial breathing therefore is a type of respiratory murmur, intermediate in character between bronchovesicular breathing and bronchial breathing. It is characterized by a type of breathing in which the expiration is prolonged and the pitch intensified as compared to inspiration but not so pronounced in type as in pure bronchial breathing. Of course this type of breathing occurs at the left apex also at times, and elsewhere in the chest when there is a pathological process manifested by change from bronchovesicular breathing to bronchial breathing.

Studying, for instance, the left apex and regarding vesicular breathing as the normal type at this apex, if it is the seat of an incipient pulmonary tuberculosis the breathing changes to bronchovesicular; from this type of respiratory murmur it changes to semibronchial and after that, generally after some time has passed, to pure bronchial breathing.

While on the subject of auscultation it would not be amiss to state that emphysematous breathing and also asthmatic breathing are abnormal types of the respiratory murmur and when heard in a pa-

tient, as they often are, present some difficulty, as they may obscure the true diagnosis. These types of breathing are generally not localized to any particular area, and very often are to be heard over both lungs. An interesting problem presents itself when such a patient, that is, one having emphysema and bronchial asthma, becomes infected with the tubercle bacillus. How can one then diagnose the condition and know whether pulmonary tuberculosis is a complication or not? One way is by the fact that pulmonary tuberculosis is more likely to be localized to areas in the chest, and therefore the type of breathing localized. In emphysema and bronchial asthma, however, a prolonged expiration predominates, and when the pitch is high it certainly is confusing, since the localized areas might be conspicuous by their absence. Nevertheless in the case of pulmonary tuberculosis supervening, one often gets the typical crepitant rale coming on, localized in character as to place, and, of course, when found, helping to clinch the diagnosis.

TRUE PRURITUS ANI: ITS ASSOCIATION WITH PYORRHEA ALVEOLARIS.

BY E. JAY CLEMONS, M.D.

LOS ANGELES, CALIF.

THE importance of focal infections as direct and indirect causes of pathology is becoming more and more evident owing to the fact that sufferers from diseases produced thereby are daily being relieved by removal of focal atria of infection without any attack being made directly on the end results of long standing secondary infections.

Pruritus ani is a symptom of a number of etiological entities because it is itching of the anal integument. Itching of the anal integument may be associated with or accompanied by a general state of bodily itching which is exaggerated in this location because of friction produced by contact of the buttocks one with the other. Pruritus of these parts may result from heat chafe, parasitic diseases or true skin lesions, as well as from excoriations produced by contact of the parts with secretions from local infections or from adjacent organs—such as the rectum, vagina, or urethra. Pruritus ani, therefore, is the symptom of itching of the anal integument from any cause whatsoever.

While it is a fact there are numerous general and local etiological entities which produce the clinical symptom of pruritus ani there is only one distinct pathological entity which is recognized as true pruritus ani. True pruritus ani is a disease, manifesting itself after the second or third decade of life, caused by the gradual percolation of infection from the rectal mucosa into the loose subcutaneous tissue of the anal integument. This disease is characterized by pruritus, corresponding to the area of skin involved. The itching is more annoying upon retiring at night and is aggravated by scratching. The parts involved lose their pigment and become thick and leathery, causing the integument of the anus to be thrown into longitudinal folds with deep fissures between them. These fissures are constantly excreting a

thin, watery, irritating fluid, which fluid keeps the parts moist. True pruritus ani, therefore, is the percolation of infection from within the rectal mucosa into the loose subcutaneous tissue of the anal canal.

Most intense symptoms are referable to the anus in this disease, while no symptoms are referable to the rectum. This is owing to the differentiation of the nerve supply at the anorectal line; above this line the rectum receives its nerve supply from the vegetative nervous system; below this line the anus receives its nerve supply from the systemic nervous system. This pathology causes no symptoms referable to the rectum because the vegetative nervous system does not transmit impulses of this disease. While no symptoms are referable to the rectum in this disease there are distinct symptoms referable to the anus because of contact of the cutis vera with infectious material which has percolated into the anal subcutaneous tissue from the rectal mucosa, bringing irritating material into contact with the highly developed nerve terminations, thereby producing the characteristic symptoms of this disease.

The organism which is the etiological factor in true pruritus ani is a streptococcus. This has been proven by the original work of Dr. Dwight H. Murray of Syracuse, N. Y. Dr. Murray* had vaccines made from the thin watery irritating fluid excreted from fissures between folds of anal integument of persons suffering from this disease by isolating pure cultures of streptococci and from these cultures making autogenous vaccines. With these autogenous vaccines the doctor controlled the symptoms of patients suffering from this disease, by immunization, without aid of other procedures, thereby demonstrating beyond doubt that streptococci are the offending organisms in true pruritus ani.

The fact that this infection is streptococcic proves it is not primary, because a primary streptococcic infection of these parts would necessarily be associated with classical symptoms of infection, namely—heat, redness, and swelling, which symptoms do not enter into the clinical picture of this disease. It therefore becomes necessary for us to look elsewhere for a primary focal infection which causes large numbers of pathogenic bacteria to assault the mucosa of the alimentary canal, causing secondary infection which manifests itself in this condition. In studying cases of true pruritus ani we find these patients suffering from pyorrhea alveolaris.

Pyorrhea alveolaris is a disease characterized by discharge of pus from the soft tissues around the teeth. This disease is caused by salivary calculi forming between the gums and the teeth; or food may crowd between the gums and teeth and undergo decomposition; or the gums may be wounded at the junction with the teeth, as frequently takes place by use of toothpicks, starting focal infections. Focal infection once started here is the beginning of this disease. The disease spreads by continuity of tissue, thereby causing the gums to recede from the teeth, allowing free exit of pus to be constantly discharged into the mouth.

*Murray, D. H.: Transactions of the American Proctologic Society.

The organisms isolated from pyorrheal pockets are most mixed and varied, but pyogenic cocci occur far more frequently than others. It has been proven* that these pyogenic cocci have their proliferation retarded, but they are not killed, by the action of the gastric juice; therefore, quantities of this pus is constantly assaulting the mucosa of the whole alimentary canal each twenty-four hours in severe cases of pyorrhea alveolaris.

All patients suffering from pyorrhea alveolaris do not suffer from true pruritus ani because all cases of pyorrhea alveolaris do not have a streptococcic infection as the etiological factor and also because certain individuals suffering from this disease have a natural resistance to the infectious material which constantly passes into their intestinal canals. On the other hand patients suffering from pyorrhea alveolaris, with streptococci as an etiological factor, having low natural resistance to the attenuated infection constantly entering their intestinal canals develop true pruritus ani.

Having patients suffering from true pruritus ani associated with pyorrhea alveolaris, it becomes necessary to carry out two distinct procedures in order to relieve them of their infections—first, removal of focal atria which keeps up pyorrhea, and second, drainage of the rectal mucosa to rid the tissues of the infection causing the pruritus ani. The pyorrheal atria are removed by extracting the teeth. The rectal mucosa is drained by removing the lateral anal cutaneous tissue, this being easily accomplished under local anesthesia, at the same time drawing down and suturing the adjacent rectal mucosa to the fascia between the external and internal sphincters, using ten-day catgut for suture material. By this procedure primary hemorrhage is prevented, and upon absorption of the sutures the rectal mucosa drains. In fact, the wounds do not heal till the parts have drained and the tissues are thereby freed from infection.

528-529 BLACK BUILDING.

*Miller: Microorganisms of the Human Mouth, 1890.

Zona Following Trauma of Spine.—Boursier and Ducastaing saw a small shell fragment wound slightly to the right of the spine followed on the tenth day by zoster in the distribution of the two nearest intercostal nerves.—*Révue Neurologique*.

Cause of Benign Albuminuria.—Oziembowski attributes this in part to vagotonia, which, however, is itself an expression of insufficiency or aphasia of the chromaffin system, this lowering the tone of the sympathetic. As a result the renal vessels become dilated, and the vagotonia is not itself the cause, but rather a concomitant of benign albuminuria.—*Deutsche medizinische Wochenschrift*.

Sensorial Functions of the Blind.—Ioteyko refers to space perception and the vicarious action of the other senses. The blind do not conceive originally of space of three dimensions. Gradually the latter is realized as is also the conception of infinity. Some blind individuals study geometry. The idea of the third dimension is probably never fully realized. Superiority in hearing and touch is not founded on superior perception but superior apperception.—*Révue Scientifique*.

Military Medicine.

SYMPOSIUM ON MILITARY MEDICINE.

THE meeting of the Section on Medicine of the Medical Society of the State of New York, held Wednesday, May 22, Dr. Arthur F. Chace presiding, was devoted to a discussion of topics relating to Military Medicine.

Classification and Serum Treatment of Pneumonia at Camp Upton.—Major RUSSELL L. CECIL, M.R.C., of the Base Hospital, Camp Upton, made this communication. The pneumonias were of two classes, streptococcus pneumonia and pneumococcus pneumonia. The former were caused by the *Streptococcus hemolyticus* or the *Streptococcus viridans*. Of the pneumococcus group, it was found, contrary to usual experience, that Type IV pneumococcus produced severe cases. The mortality in Type I cases was high in those not receiving serum. In Type II cases the mortality was also high. Of all cases, those caused by the hemolytic streptococcus were most severe and the mortality highest, reaching 40 per cent. This infection was also the most common one, more than half the cases being caused by this organism. The symptomatology was atypical. There were fever, chills, pain in the chest, very little expectoration, and the sputum was not rusty or blood tinged. The physical signs were often indefinite and percussion of the chest gave negative results. On auscultation moist rales were heard. The voice and breath sounds were hardly changed. One group of cases showed mixed infections, a pneumococcus being present early in the disease and later a hemolytic streptococcus. In this type marked prostration was present. The x-ray picture was characteristic, showing small spots over the lungs characteristic of military tuberculosis. These corresponded to the pathological findings by Drs. Cole and MacCallum. The cause was apparently proliferation of the lymphoid tissue at the bronchioles. In regard to complications, the cases were often followed by empyema, of one of three types: pneumococcus empyema, streptococcus empyema, or sterile empyema. The first type developed early in the disease. Fifty cases out of eighty were streptococcus empyemas—hemolytic or viridans. The sterile empyemas showed distinct purulent fluid. The surgical treatment of empyema was a problem which was not entirely settled. So far the best results seemed to have been obtained from thoracotomy with free drainage and irrigation with the Dakin solution. In regard to the serum treatment, one half hour before injection a 5 c.c. desensitizing dose of normal horse serum was given, followed by intravenous injection of the specific type serum, by the gravity method. Types I and II serum had been used with success. The use of the polyvalent serum had been attended with high mortality, and had therefore been discontinued. There were some cases of serum sickness, and two cases of anaphylaxis, both of the latter following injection of the polyvalent serum. In one of these cases the patient had been given one dose, and ten days later, in the height of sensitiveness, he had a relapse. The laboratory man, not knowing the patient had had a previous dose, gave another dose of 50 c.c. The patient did not survive five minutes. The desensitizing dose had no effect in protecting the patient. With proper precaution such accidents could be avoided. In regard to prophylactic vaccination against pneumonia, this had been tried with half the troops in camp, the other half not being vaccinated. A medical man was sent with the troops to the other side especially to study their immunity. In ten weeks the results among the vaccinated cases showed 17 cases of pneumonia against 173 cases among the non-vaccinated troops. There was also evident a certain cross protection against streptococcus pneumonia by the pneumococcus vaccine. This might be explained by the fact that very many cases were pneumococcus at the outset. As far as the cases had been followed, it would seem that a certain amount of immunity had been conferred against both the streptococci and the pneumococci.

Dr. A. F. CHACE of New York said that the boys in camp were receiving better attention than they would in civil life. The study of pneumonia had been distinctly advanced by the military viewpoint. He would like to know how long it took to make an accurate diagnosis.

Dr. L. C. AGER of Brooklyn asked what was the difference in the results by the Avery and the mouse method. He thought that from the point of classification it would be clearer to call the streptococcus condition "pneumonitis" rather than pneumonia. Pathologically there was pneumonitis rather than consolidation. He would like to ask what was the best time for operation in the streptococcus pleurisy which occurred at the height of the disease. Did they operate at that time?

Dr. H. WILLIAMS of Buffalo asked if the large percentage of Type IV cases had anything to do with the use of the Avery blood broth media instead of the mouse. If the strains had been typed by injecting into a mouse the greater virulence of other types would not have appeared. In the Avery blood broth the different types would grow indifferently.

Dr. E. L. FROST of Buffalo asked how many doses of the serum were usually used.

Dr. H. WEISMAN of New York asked what was the method employed with the use of the Dakin solution in empyema.

Lt. BRAISTEAD, M.R.C., of Cornell asked would the blood broth give as good result as the mouse injection in cases where there were no laboratory facilities for using the latter method.

Dr. M. PACKARD of New York said that they had had a great number of pneumonias at Gouverneur Hospital. There were very many Type IV cases and many streptococcal cases. Type IV pneumococcus was a normal inhabitant of the mouth and was probably agglutinated by Type IV serum. The complications were unusual. They included parotitis, arthritis, acute psychosis, and many empyemas. With empyemas the mortality was the same whether the cases were drained or not drained, that is 35 per cent. Cultures showed *Streptococcus hemolyticus*.

Major R. L. CECIL said he had to slide over many points as the subject was so large. He had not got the figures as to the comparative value of the Avery and the mouse methods. He had started out with a prejudice against the former, but when once one was familiar with it, one got better results. He used the agglutination test, but if one had a high speed centrifuge the pneumococci could be washed out with blood and bile and the precipitin test could be used. To determine the organisms they were plated out on blood agar. An accurate classification was obtained, but it took 48 hours. Using the mouth method one could make much better time than that. There had been, however, remarkable coincidence in the mouse and blood broth methods. Hemolytic streptococci would sometimes be missed in the mouse, where they could be detected in the blood broth. As to the Type IV, Dr. Stillman had suggested they might be mouth pneumococci. The incidence was very high in the camps. In the empyemas seven cases had Type IV in the sputum and pure culture in the pleural fluid. If there were any error it would have been discovered in these cases, where often the bacteriological work was verified by autopsy findings. In regard to the serum, usually three or four doses were given, sometimes as many as six. In regard to Dakin's solution, he had not been in close touch with the surgeons, but he thought that not much resection was done. They made a large incision, and injected by gravity. As to diagnosis of streptococcus pneumonia, it could be made by clinical signs, once one was familiar with the disease. They were not expert enough at yet to diagnose the type by clinical signs.

Brief Outline of Personal Observations in Italy and at the Western Battle Front with the American Red Cross.—Major ALEXANDER LAMBERT, M.R.C., of the American Red Cross, made an interesting communication on this subject. He had not, he said, been stationed with troops, and would not give a detailed description of camp medical organization, but rather present a series of general personal impressions, gathered during his work with the Red Cross Commission. First, in regard to the incidence of disease among the soldiers, 32 per cent. of cases of infective disease among troops were meningitis and pneumonia. The pneumonia was identical with that described by Major Cecil. The patient was very sick, highly toxic, with less breathing than one would expect to find and a peculiar high-pitched breath sound on the left side.

The chest was filled with fine rales. The patient evidently had pneumonia throughout both lungs, the right side evincing the peculiar sound that told of central consolidation under the tip of the scapula point. English medical men mentioned a peculiar septic bronchitis, apt to develop into pneumonia. Colonel Elliott had asked the Research Committee of the Red Cross to investigate this subject, but so far the work done upon trench fever had occupied their entire time. In regard to meningitis, it was found that various strains were responsible for the infection, so that a serum for one strain did not help in infection by another. This caused considerable difficulty where there was only one type of serum obtainable. In July, 1917, in Belgium, Dr. Lambert said he had observed many cases of Weil's disease, infectious jaundice; this was a spirochetal infection, but in at least 30 per cent. of the cases no jaundice was shown. The disease was most serious and in the beginning there were severe hematemeses and hemorrhages from the bowel. The anemia was extremely grave. Spirochetes were frequently demonstrable in the blood stream.

In regard to *trench fever*, this was a subject which had demanded a great deal of attention. It had caused great disturbance in the English Army, owing to the fact that as many as 10 per cent. of the men were sometimes put out of commission by it. The disease often started with tingling in the hands, fever, malaise, and pains in the bones and at the insertions of the muscles. The temperature ran high for three or four days, then subsided, and there were later exacerbations of the attack for a few days at a time. The course of the disease ran for many weeks, and then, in young, robust men tended to clear up. With men over 40, a chronic type of the disease was apt to set in. The temperature ran subnormal, the pulse dropping to 60 or even down as low as 44. Dr. Lee of Boston collected charts of 200 chronic cases and in these it was shown that the temperature rose to normal only during the exacerbations, that is to say, at the times when it would formerly have risen to 103° or 104°, and the pulse only rose to 72, instead of to 120-130. Dr. Swift found that the day before the exacerbation the patient's spleen became enlarged. No small laboratory animals were susceptible to the disease. It seemed to be in the blood. The work of the American Red Cross Research Committee was directed to this condition and General Bradley, chief surgeon, gave unstinted help. Volunteers offered themselves for experiment and it was found that persons injected with whole blood from infected patients contracted the disease. Centrifugalized blood gave the same effect. With filtered blood, the organism apparently remained with the corpuscles and did not pass the filter. Transmission by the body louse was suspected and lice from infected persons were allowed to bite the volunteers, who soon came down with the disease. Lice were then brought from England, where there was no trench fever, and put upon trench fever patients. They were then put upon healthy persons who in turn came down with the disease. Put upon another person, they again transmitted the disease, and so on to a series of persons. The lice were kept in a little cell, strapped on the arm over an old piece of undershirt. The men were allowed to scratch, so that normal conditions were reproduced. The organism producing the disease had not so far been discovered. It had not been stained. It might be that it was a filterable virus. Transmission by this insect having been proven, the question of "delousing" the army was before the authorities. This was a stupendous task, but it was not impracticable. With proper measures for cleanliness and sanitation, it could be done. The French had invented a system of portable baths in which from 800 to 1000 men could be bathed. With proper bathing and clean clothing the vermin, and thus the disease, could be eliminated. It was simply a question of sanitation and engineering.

Gas poisoning cases so far had not been seen in this country. In July, 1917, in Belgium, Dr. Lambert had seen 40 men suffering from "mustard gas." Phosgene gas (COCl_2) was also used for gassing. It had a slightly sweet odor. Some few hours after inhaling it the men went to sleep and died in sleep. It did not cause immediate symptoms. It was apt to enter the dugouts and poison the men there. The effect of the gas was

upon the heart muscle, which became degenerated; it caused sloughing of the lungs with exudation of blood into the air spaces, and a solid leathery lung was produced. Patients suffering from this poison had to be kept absolutely quiet. They could not speak or move. After some weeks, if kept perfectly quiet, they usually recovered. The first cases of poisoning occurred in two orderlies who went to examine a shell which had exploded with a peculiar noise. They probably inhaled gas from the shell. Next morning they were found dead. The lacrymatory gas was a bromide variety; it caused intense coughing and irritation, especially of the eyes. With the first use of chlorine gas the Germans nearly got through to Calais. The ground was held by North African and Algerian troops, who succumbed to the gas and died like flies. Two Canadian and British regiments kept their heads and stood their ground. It was a terrific experience, but enough of them lived through it to hold the day. The British gas mask protected against phosgene gas and mustard gas (dichlorethyl sulphide.) In the latter the chlorine element apparently broke loose and did injury by absorption. Terrific blisters of the skin were produced by this gas, also inflammation of the bronchi, trachea and larynx, and inflammation of the eyes. The whole mucous membrane of the larynx and the bronchioles was apt to slough out and the patient choked and drowned with the exudate. Unless abscesses of the lung resulted from loss of mucous membrane the cases usually recovered in a few months. The gas usually leaked down through the clothing to the belt, blistering the whole trunk, but if the belt was tight it stopped the progress of the blistering. A circular line of blistering was shown round the body. Bicarbonate of sodium (or any alkali) was of great use in prevention of blisters. In one case where there was no water to make a solution, the officer ordered the men to rub dry bicarbonate on their heads. This ran down with the sweat and saved the men from blistering after a gas attack. Great care was necessary on the part of doctors and nurses in undressing these patients. The gas escaping from the clothing was apt to cause severe blistering in those doing the dressings. In removing the gas mask care should be taken to do so slowly. The mustard gas gave a yellow tinge to the earth where the shells exploded or to banks where it fell. Soldiers found out by experience that it was not safe to sit or lean on this earth, as they became blistered with the contact. The dugouts had to have a curtain in front of the door to prevent entrance of the gas and men in front of the dugout used fly swats to beat off the fumes before entering.

Referring to the *Italian situation*, Major Lambert said he had gone to that country shortly after the débacle occurred. The Red Cross sent men to see what was the best way to give aid in the crisis. Base hospitals established behind the Piave line were in readiness to move their patients upon telephone summons. Hospitals of 1,200 to 2,000 beds became forward dressing stations. The bridges were mined with dynamite, covered with layers of sand, and chauffeurs were quite ready to drive slowly when warned of the situation. The Italian hospitals were beautifully clean, thoroughly well equipped, and entirely scientific and up-to-date in every way. The laboratories were well supplied with sera and materials for research. There were pneumococcus, meningitis and tetanus antisera and vaccines for typhoid, cholera, etc. The Italian Red Cross lost a great deal of its stores in the reverse. The troops and supplies depended upon a single system of transportation, and in the rush the transportation broke down. However, two million men and their supplies got across, the last medical stores only being left. The Italian bersaglieri could be spoken of in the terms of highest admiration. They fought their way back, although some companies were lost sight of for days, but they rejoined their own commands. The Italian cavalry troops of Genoa tried to stem the rout and could not. They determined to show the army how gentlemen could die. They dressed in their full dress uniform, a very handsome one, and mounting horse rode against the Austrian machine gun batteries—a suicidal act; but with desperate courage they took the batteries and about half of their number came back with the guns. The rest were annihilated.

In regard to the *surgery of the war*, Major Lambert said that he thought a medical man could give a general outline of results. At the beginning of the war the septic condition of wounds beggared description; it was something terrific. The effort was made to transport the wounded to a distance. Then it was seen that the nearer the hospital to the lines the better the chance for the wounded, so that hospitals were established eight or nine miles behind the lines. Great reliance was placed on antiseptics during transportation. Finally, Lemaître and Duval found that the detritus, forced into the depths of wounds, was the cause of the sepsis. The muscle tissue itself, if the contractile power was injured, had to be removed, so that large masses of dead tissue had to be cleaned out. Finally the wound was washed with the Carrel-Dakin solution. After this "débridement," as it is called, the wound was stuffed with sterile gauze, and later could be sewn up, to heal by first intention, often within three weeks. The only exception to this was that where streptococci were isolated from wounds it was not safe to sew the wound up. The main idea held now was "better surgery and less antiseptics." Brilliant results had been seen with the Carrel-Dakin method in many cases. Treatment of wounds had recently advanced so that a compound, comminuted fracture could be changed to simple fracture. The work of Jones in England and of Blake in France had reorganized methods of treating fractures, but it was found that there was a tendency to go back to old and well tried methods of traction and posture in dealing with fractures. The subject of gas gangrene was of interest. Infection by the Welch bacillus was found to travel in a direction parallel with the fibers of the muscles, under the sheaths. The organism lived on the glycogen of muscle. The infection sometimes had to be followed along as far as the insertion of the muscle, and enormous masses of tissue had to be cleaned out to get rid of the gangrene. Sometimes cutting the muscle across arrested the path of infection.

The Red Cross Research Society had met once a month to study all these questions. The French and British surgeons had met with the American men and facts gathered by experience of four years of war had enabled the American surgeon to begin with 1918 ideas of war instead of learning from the start. Absolute cooperation existed between the surgeons of the different allies. The work of the Red Cross had always been of primary importance to the army. All else was secondary. First, last, and all the time the Red Cross and the army were in unity. The cooperation could not be more close than it is. There had been some misunderstanding regarding the Research Department of the Red Cross. The Red Cross, through Major Murphy, started a research fund. Some criticism then arose on the part of Christian Scientists and antivivisectionists. Therefore it was thought wise not to use the general fund and a separate research fund was organized. Major Lambert said he had control of this branch and that the work had gone on and would go on without interruption. Every cent needed had been given and given without question. The administration work was hard and meant building up and organizing and getting others to do the work outside. The work, however, would get the necessary funds, and it would continue in spite of everything.

Dr. A. F. CHACE of New York said that physicians thought that medicine would be at a standstill, as compared to surgery, in the present war. They had been much enlightened by Major Lambert's remarks. The constructive work that was going forward in the camps and trenches was a great credit to the United States Army. The addresses this morning dealt with three aspects of the question—work going on abroad; work going on in the United States; and the position of the physician in civil life as regards the war. The latter phase of the subject would be covered by Dr. Cox, in his presentation on the "Albany Idea."

The Albany Idea.—Dr. JOSEPH AMBROSE COX of Albany presented this report, a historical review of work accomplished since November, 1915, when a group of men in Albany considered the serious possibility of war breaking out and started to obtain necessary knowledge of medical military matters. They set themselves to study the problems connected with this subject and to collect data concerning the medical

military resources of the whole country. Such subjects as camp hygiene, sanitation of troops, writing and interpreting of orders were considered. Emergency problems were studied, such as: (1) Water supply: If New York and Boston were taken and troops retreated on Albany, what steps could be taken to protect the water supply? (2) Medical supplies: The management of medical supplies and stores necessary to care for a large number of refugees. (3) Wounded: The possibility of 10,000 wounded being thrown into the city. In working out such problems the resources of the community were investigated—what the hospitals could do, were they adequate; where supplies were to be obtained; what number of nurses and doctors could carry on activities. The answers to many of these questions had been worked out and the plan was published by the Clinical Club of Albany as a plan of military instruction, the details of the scheme being given in the pamphlet. [See MEDICAL RECORD, April 14, 1917.]

Dr. A. JONES of Buffalo said that Dr. Lambert referred to trench fever. Was it true that the bite alone of the louse could transmit the virus? Dr. Jones said he understood Dr. Opie to say at Atlantic City that the virus was not transmitted unless the men scratched, and that by this means the excreta of the louse were rubbed into the skin and caused the infection. Dr. Lambert had not particularly mentioned medical matters on the Italian front.

Dr. J. L. WILLIAMS of Rochester said that "mustard gas" was invented by a chemist, now working in Rochester, and then employed by Fischer in Berlin. The phenomena Major Lambert had described were discovered accidentally. The name was used no doubt because mustard gas contained no mustard and was not a gas.

Dr. R. H. Sayre of New York said he thought the Albany idea was a remarkably good one. It showed the advantages of preparedness instead of waiting until an accident happened. It made one realize the vast amount of ignorance in regard to conditions with which one was surrounded. A year ago the chief surgeon of the Police Force called a concourse of surgeons and put such questions to them as: "If a great catastrophe happened, what could the hospitals do?" "If an explosion occurred in the Grand Central Station, how would the people be transported?" "If a large part of the city were destroyed and it were necessary to make villages on Long Island, how could people be cared for?" "If the aqueduct were broken, how would the water supply be provided?" Preparations were then discussed to meet such contingencies. Hospitals set aside a large number of wards that could be used immediately in case of emergency; the water supply for a large emergency village was considered; arrangements were made to notify a large number of doctors and nurses in case of serious emergency. It would be well if all persons would prepare themselves for any contingency that might occur.

Dr. A. F. CHACE said that copies of the reprint on the Albany idea could be obtained by writing personally to Dr. Cox.

Dr. ALEXANDER LAMBERT, in answering Dr. Jones' remark, said that he had not had time to pay attention to clinical aspects on the Italian front. He was being hurried through to help from an administrative point of view. In the sudden crisis Italy lost two-thirds of her material and supplies. Train loads of material were rushed through from Paris to tide over the situation. The chief surgeon of the Red Cross at Padua had said that if he could get microscopes, blankets, and trucks, he could manage the rest. In regard to mustard gas, the burn looked like the effect of a mustard plaster left on too long. This might have given the name. It was discovered in Berlin in 1886 and then forgotten. It might not be gas, but it would get into every place. If the gas mask was not put on quickly enough it would blister. It caused nausea and vomiting as well. The English had lately been using an emetic gas and as soon as that had had time to take effect they put over doses of poison gas, so that the Boches got a heavy dose. That might have been the reason that the Kaiser recently stated that it was not nice to use poison gas in war. An interesting fact was that at the former Hague Con-

ference two nations refused to sign an agreement not to use poison gas in war—Germany and the United States. Captain Mahan of the United States Navy refused on the ground that it was no worse to use poison gas than high explosives to kill the enemy. Theoretically this was correct. War being deadly, anything in open fight was fair game apparently. Killing the wounded and other savage tricks were not civilized warfare. In regard to trench fever, the single experiment in London had not been regarded as conclusive and the question was to be brought up for discussion at the conference to take place in Paris. As to the call of the United States for medical men, the army was in need of volunteers and medical men had responded generously. The English had made a great mistake in closing medical schools. It would be a crime in this country and there were men who would do as patriotic a duty if they simply stayed at home and kept the medical schools going. This was as needful a work as going abroad and had no *réclame*, it was just plain every day duty. There was no risk and no excitement. On the other hand the draft law must be met. Men should respond to the call of duty and those who answered deserved full credit. Major Lambert said he had been more and more impressed with the moral effect produced by the entry of the United States into the war. It was far greater than was ever realized here. On the other hand the physical effect had been far less than was anticipated. The greatest task of history was now laid upon the United States. A huge army must be produced and a well organized medical corps to handle it. If sufficient volunteers were not found, there should be a forced draft. The amount that had been done was nothing to what would have to be done. The whole spirit of the country had been changed, but still there was as yet little realization of the hugeness of the task and the tremendousness of the bitterness that would have to be paid. The French profession had answered the call. Not one medical man under 65 years was out of the army. The older men were taking care of patients in remote country districts. Physicians as old as 85 years were working for these country patients. Women physicians were doing splendid work among the civil population and in caring for children. There was a great field of usefulness for them in this work. One unit in the devastated district south of the Somme had asked for supplies and help. They had fallen back from St. Quentin and the Lys with their patients and had spent two nights operating on soldiers without anesthetics. Even a disarticulation of the hip was done without anesthesia. The Red Cross rushed five truck loads of supplies up to them. The Scottish women physicians had done splendid work in that region also. In obstetrics in Belgium, and in pediatrics there was a great work for women physicians.

American Red Cross to Help in Switzerland.—The American Red Cross officials are preparing to organize a force of workers in Switzerland to assist the Swiss Red Cross, which is overwhelmed with relief work since the badly wounded and sick contingents of various nationalities and civilian refugees are being repatriated. The American Red Cross has established large relief stations on the Buchs and Gothard railroad to attend to Italian prisoners while they are being exchanged.

New Beth Israel Hospital for Government.—The Beth Israel Hospital Association, New York, has offered to the Army and Navy Departments the new fifteen-story hospital building which it has planned to build on the black fronting Second Avenue, between Seventeenth and Eighteenth Streets. The plans provide for a hospital building to cost \$1,250,000 and fully equipped to care for 500 patients. Both the Army and Navy Departments have the proposition under consideration. If it is accepted the work of construction will be rushed. The Beth Israel Hospital Association

has been preparing to erect a new home for some time and it believes that by hastening the work it will do a patriotic duty. The offer is for the period of the war or longer if necessary.

Conference on War-Time Problems.—The War Service Committee of the American Hospital Association will hold a conference at the New York Academy of Medicine, New York City, June 3, at 10.30 a. m. The tentative program on hospital problems resulting from the war includes a discussion of income and expenditures, new construction, medical and surgical supplies, medical service, nursing service, care of Government patients, and cooperation with the Federal Vocational Board and the War Risk Insurance Bureau.

Misstatements of Antivivisectionists.—Dr. W. W. Keen of Philadelphia calls attention to two erroneous statements made by the antivivisectionists in the resolutions which they passed on January 31 last. The first of these resolutions demanded that "it be left to the free will of each soldier as to whether his health and life should be endangered which, in actual experience, had resulted in deplorably affecting the strength and availability of our National Army and occasioned unnecessary loss to thousands of American families who had bravely offered their young manhood to our beloved country." In refutation Dr. Keen points to the fact that antityphoid vaccination has practically banished typhoid fever from our own cantonments and also from the armies in Europe. In the British Army in France 99 per cent. of the soldiers have voluntarily sought its benefits. The second resolution "points to the provision of exemption now made by Great Britain, that power having been forced to rescind the rule of compulsion after the alarming effects of inoculation were disclosed." The statement in this resolution is also untrue. Dr. Keen cabled to Lieutenant-General Goodwin, Surgeon General of the British Armies, "Has antityphoid vaccination ever been compulsory in the British Army?" To this he received the reply "Antityphoid inoculation has never been compulsory in the British Army."

The Government to Take a Department Store Building for Hospital.—Government representatives have inspected the store building formerly occupied by the Siegel-Cooper Company and later by the Greenhut Company on Sixth Avenue, between Eighteenth and Nineteenth Streets, with a view to taking it and fitting it up as a base hospital for invalid soldiers. The building contains twenty-three acres of floor space and can accommodate 3,000 soldiers. The plans contemplate using it for medical cases and as a distributing base.

Navy Needs Hospital Helpers.—The navy is in urgent need of men for the hospital corps. Men need have no special knowledge to enlist as hospital apprentice, second class. Graduate pharmacists or nurses may be enlisted as hospital apprentice, first class. Advancement is very rapid. Further information may be obtained by applying to any navy recruiting station.

Dr. Kate B. Karpelas has been appointed acting assistant surgeon to the Emergency Dispensary of the Medical Department, U. S. A. This dispensary is for the medical care of the civilian employees of the War Department.

MEDICAL RECORD.

SIMULTANEOUS MULTIPLE INTESTINAL INTUSSUSCEPTIONS.

USUALLY, in cases of intussusception, invagination takes place at only one point; but occasionally it occurs at two points and sometimes the overlooked second point of invagination accounts for the death of the patient after early operation and easy reduction of one, and what is supposed to be the only, intussusception. Cases in which there are three or more points of intussusception simultaneously are certainly extremely rare and reports of but very few such cases can be found in the literature.

In the March, 1918, number of the *Archives de Médecine des Enfants*, there is an abstract of a report by Dr. Prudencio de Pana (*Arch. Lat. Amer. de Pédiatrie*) of a very interesting case of this sort. The history of the case pointed plainly to intussusception which had quite evidently existed for six days, and an operation was performed. The greater part of both small and large intestine was found collapsed. A violet-black, cylindrical tumor (intussusception), 10 to 15 centimeters in length, was found starting near the duodenojejunal angle. As the invagination could not be reduced, the bowel was resected and anastomosis performed by the Murphy button method. The child died eight hours later. At autopsy a second invagination, situated about 35 centimeters from the ileocecal valve and easily reducible, was found, and also a third invagination, ileocecal and appendicular, likewise easily reducible. It was further discovered that the child had a single horse-shoe kidney.

Because of the long delay in recognizing the nature of the case and deciding upon operation, with the result that intestinal resection at the duodenojejunal angle became necessary, and because of the complicating purpura, it is likely that the child would have died even if the other invaginations had been reduced; for but very few cases where resection has been done for intussusception have survived. The especially interesting features in this case were the long delay in arriving at a diagnosis of intestinal obstruction of some sort, the triple, simultaneous intussusceptions, a concomitant purpura hemorrhagica, and the additional fact brought out at autopsy that the child had a single horse-

shoe kidney. Certain facts regarding intussusception apparently need to be repeatedly emphasized; and while the symptoms in the above case were in some respects atypical, we may take this opportunity to call attention to a few points.

First, the physician who is familiar with the symptoms and clinical course of cases of intussusception should rarely be long in doubt as to the correct diagnosis; for the variety and sequence of symptoms are, or at least should be, easily recognized. Usually the symptoms are approximately as follows: A previously apparently perfectly healthy baby has sudden, severe abdominal pain, accompanied by pallor, shock, and vomiting. The bowels may or may not move normally at this time. After the first stormy onset there is usually a period of deceptive calm lasting minutes or hours. This is followed by further and persistent vomiting, together with rhythmic straining accompanied, after a few hours, by bloody and mucous stools; while in almost all cases a tumor may be felt either on abdominal or on rectoabdominal palpation.

Second, the mortality in intussusception is disgracefully high and for but one reason, namely, delay in the reduction of the invagination by operation. This may be due to (1) diagnostic errors, (2) procrastination while the usually deadly so-called palliative measures are attempted, or (3) refusal of the parents to consent to operation until it is apparent that the child is rapidly losing ground. The reduction of intussusception by early operation is one of the easiest and most thoroughly satisfactory operations in the realm of abdominal surgery; and that under such conditions the mortality may be nil is shown by Clubbe's series of 25 consecutive early cases without a death. With delay the mortality percentage rapidly rises; so that in hospital statistics, taking the cases as they come, whether operated upon early or late, a mortality of 50 per cent. is not at all uncommon, while in many instances it is even much higher.

Third, since delay in calling the surgeon is thus so likely to result in an unnecessary fatality, we would emphasize the fact that responsibility in cases of intussusception rests primarily upon the general practitioner and only secondarily upon the surgeon. It is only when the surgeon is called early and fails to discover and reduce multiple invaginations, if they exist, or otherwise fails to handle properly the entire pathological condition that the responsibility for a fatality is justly his.

THE RÔLE PLAYED BY LICE IN THE CAUSATION OF DISEASE.

IT has been demonstrated both experimentally and clinically that to the body louse is due the transmission of typhus. If not the sole means of transmission of the disease, at any rate, the louse is a main factor in conveying it from person to person. At the present time, this question of the transmission of disease by the agency of lice is of the

first importance, since soldiers in the trenches are constantly infested with them, and it is easy to imagine that if lice are infected, disease may be transmitted on a wide scale and with disastrous consequences. It is not known absolutely that diseases other than typhus can be transmitted by lice, but it appears probable that there are some. For example, suspicion, almost amounting to conviction, has fallen upon the louse as a means of transmitting relapsing fever, and it will be instructive to quote Professor George Nuttall (*Parasitology*, 1917, vol. 10, No. 1) on the subject, more especially as the facts are by no means well known and frequently misrepresented.

Nuttall draws attention to the fact that epidemiological evidence, as in the case of typhus, points to relapsing fever being louse-transmitted. The two diseases occur under like conditions; personal filth and squalor, the close contact of persons through overcrowding, facilities being offered for the propagation of lice by the continuous wearing of clothing day and night for weeks or months on end. All recently collected evidence from India, North Africa, Germany, Russia, and Serbia prove that lice are constantly present on infected persons. These remarks apply with equal force to typhus, which may coexist with relapsing fever in epidemic form. Judging from accessible records, relapsing fever appears to be somewhat more restricted than typhus in its geographical distribution. It has been conclusively demonstrated by carefully conducted experiments that *Pediculus humanus* serve as a carrier of *Spirochæta recurrentis*, the causative agent, from man to man.

Spirochetes are transmitted hereditarily in the louse, for the offspring of an infected female has been shown to be infective. The persistence of the spirochetes in the louse no doubt serves to maintain them in nature. The infectivity of the louse does not depend upon the presence in its body of visible spirochetes, in fact, it has been shown that when spirochetes reappear and attain their full size the lice are non-infective. This coupled with the observation that human blood is infective during the apyrexial stage when spirochetes cannot be found in the blood, bears out the view that Nuttall and others have upheld, that spirochetes are protozoa, as they obviously undergo a cyclical development in both the vertebrate and arthropod hosts.

The most interesting part of Nuttall's paper is that which discusses the manner in which lice transmit infection. It seems to be generally believed or assumed that they convey infection by biting. According to Nuttall, such is not the case. It has been proved that lice do not convey relapsing fever by their bites. Infection takes place through the lice being crushed upon the skin which is commonly excoriated by the self-inflicted scratches of the individual harboring the lice. Infective material may, moreover, be carried on the fingers to the nose or eye, and it has been demonstrated experimentally that the spirochete is capable of in-

vading the system through intact mucous membrane. The period of incubation, under experimental conditions as observed in man and monkeys following infection through the excoriated skin or intact mucous membrane is 6 to 8 days, when crushed lice in the infective stage are used. This corresponds with clinical experimentation. A single infected louse, crushed upon the excoriated skin, has produced a relapsing fever. Men have been experimentally infected by placing infected lice upon their persons without their knowledge.

MINERS' CONSUMPTION AND PULMONARY TUBERCULOSIS.

THE special tendency of certain occupations to cause disease has long been known, but it is only within comparatively recent times that the subject has received sufficient serious thought to lead to careful study and the institution of preventive measures. All vocational diseases reduce individual efficiency, the efficiency of the work at hand, and the general well-being of the community, and it is evident that the cost of sickness is far greater than the cost of installing protective mechanisms. This, indeed, is now the stand taken by most large and progressive employers. Miners' consumption has, however, a special sanitary interest because the disease is confounded with actual pulmonary tuberculosis, and because, in fact, it is so often accompanied by pulmonary tuberculosis. The likelihood of the sufferers transmitting the disease to those who have a special susceptibility to it because of the damage to the lung tissue by the mine dust becomes a general health menace. But although often mutually complicating and frequently accompanying each other, miners' consumption and pulmonary tuberculosis are not identical; indeed, they need never occur together. But in the terminal stages of miners' consumption pulmonary tuberculosis is so common that they may then be considered identical.

Miners' consumption is essentially a fibrosis of the lung tissues, the result of irritation of the lung by the dust particles. In consequence of this fibrosis there is a reduction of the alveolar cells with a proportionate reduction of the air space of the lung. The ever-present dyspnea is then a natural consequence. More particularly, pneumoconiosis is a chronic interstitial inflammation of the lungs, more marked in the apices, but present almost anywhere in the lung to marked degrees. The lung may even be almost entirely filled with fibrous nodules, each having embedded within it some of the dust particles causing the fibrosis. The surrounding lymph glands are similarly affected, the dust particles being brought to them by the leucocytes. It is evident that tissues so profoundly affected by foreign matter make a good field for the development of other infections, and tuberculosis is the most common of them. But except in the more advanced conditions these patients look well, whereas in lesser degrees of simple tuberculosis involvement the patients would be in much worse physical condition.

Pain is very common in miners' consumption as a result of the mechanical irritation of the finer bronchial tubules by the dust particles. Neither is loss of weight marked in miners' consumption except in the terminal stages. However, when the cough is very marked it usually means an infection with tubercle bacilli. In any case, the sputum is usually loaded with the dust particles and is colored in accordance with the particular kind of mine dust it contains. But in pneumoconiosis, even in advanced cases, there are few, if any, physical signs. Physical examination of these patients is in itself insufficient to establish the diagnosis, without the assistance of the history of the predisposing occupation. Very often even patients who have a complicating tuberculosis in which the sputum is positive for tubercle bacilli will present no physical signs of either disease. Usually tuberculous infection is a terminal condition, but when it occurs earlier it forces a more rapid downward progress of the disease than would occur without this complication. In miners' consumption with the tubercle complication it can never be said that the tuberculosis of the lungs is incipient. It assumes immediately the far advanced stages. Ordinarily the incipient stage of pulmonary tuberculosis is drawn out. Here its length is a negligible quantity, and the outlook for the patient is hopeless. The tubercle infection may arise from an outside source acting upon injured lung; or the tuberculosis may be a reawakening of a dormant focus.

The form of diseases included under the term miners' consumption includes all pulmonary fibrosis caused by the injurious effect of dust particles. Mine workers, marble polishers, and the like, are all subjected to the same conditions and likely to contract this disease. Unless there is a concerted move to control the conditions causing the disease by employee and the community, many more individuals must be affected as these industries continue to develop. Most health authorities make vocational diseases reportable, and legislation is even at present seeking to control the evil.

SEVERAL KINDS OF SLACKERS.

THERE are very few slackers in the medical profession; indeed, instead of speaking of several kinds of slackers in its ranks, we might merely say that there are several slackers among the 150,000 physicians in the United States. But it is useless to deny the fact that here and there in our vast country there exist medical slackers—not among our own friends and acquaintances, of course, but somewhere in the communities in which we live. In order that we may deal with them adequately, it is well to be acquainted with their wiles.

Perhaps the prevalent idea of a medical slacker is one who does not offer his services to either the Medical Reserve Corps or the Volunteer Medical Service Corps, or who does not buy Liberty Bonds. But there are doctors who are legitimately excused from military service, either because of dependents

or for other adequate reasons, and who have the financial sense to see what a good investment the Liberty Loan is and have put a sufficient amount in it to be free from reproach. And yet these same men may be slackers. We have heard of doctors who have had commissions in the Medical Reserve Corps before the war, but resigned at the commencement of hostilities, or who were found ineligible for one reason or another and yet retained the official parchment proclaiming them officers in the United States Army. These pseudo-soldiers have taken pains to have their commissions framed and displayed prominently in their offices for their patients to admire. We are told of cases where, at the opening of hostilities, the cream of the profession in certain towns would rush to join the Medical Reserve Corps. Then from the surrounding country would creep into that town several faint-hearted, greedy slackers, gladly leaving the precarious pickings on which they had been living in the country to fatten on the practices left by the patriots. "Where the carcass is, there are the vultures gathered together." We have heard of doctors who have sent exorbitant bills to the families of soldiers away in the trenches; and we have heard of other instances of greed and deficient patriotism, but they are all rare exceptions and are recruited from the same class of men we find among the medical outcasts in every community.

The vast rank and file of the profession has given its time and money freely to the cause, and it is the duty of those who have not been able to go to the front to see that when the military surgeons return to the practices they have been forced temporarily to abandon they have not suffered from the depredations of slackers.

PARAMEDICAL INDUSTRIES IN FRANCE AFTER THE WAR.

BARDET discusses this subject in the *Bulletin général de thérapeutique*, for March, 1918. He refers to the trade in French mineral spring waters and to the pharmaceutical industry, and the term is extended to include other activities such as the medical book trade and the surgical instrument and laboratory apparatus industries. At present we hear on all sides the statement that native resources must be developed. The Germans before the war were in control of the chemical, dye stuff, and perfumery industries. The war has naturally given an impetus to French chemistry, and enormous quantities of chemicals for war purposes have been manufactured. The same statement is true of the other warring countries, and this movement in its totality means the death knell of German chemistry as a monopoly. But one country at war, Japan, has been able to make war chemicals for export, and already it controls its own market for drugs, chemicals, dye stuffs, and perfumery. Labor is still cheap in that country while in all others wages have risen enormously, and it begins to look as if Japan is destined to supply much of the foreign markets in these products. French industries of all kinds will suffer for lack of coal, but the latter is not everything, for intelligence and dexterity are the real forces behind manufacturers. The French have

long excelled in the fabrication of instruments of precision, jewelry, fine watches and clocks, and similar mechanical apparatus, perfumery, medicaments, and artistic work of all kinds. These industries do not depend wholly on steam and electric power and can thrive without large amounts of fuel. Moreover, owing to their small bulk, such products require fewer ships to export them—for we must not forget that the French will emerge from the war with a greatly reduced merchant marine.

News of the Week.

Conference of Public Health Officials.—The sixteenth annual joint meeting of the United States Public Health Service with the State and Territorial Health Officers will be held in Washington on June 3 and 4. The sanitation of extra-cantonment zones will be discussed and reports made as to the success of the cooperative arrangement developed during the past year for preventing the exchange of disease between civil and military populations. All communicable diseases will receive more or less consideration in their relation to the public health during the war. Other subjects will be the relation to public health of industrial hygiene and sanitation, especially in war industries, the use of the records of drafted men for public health purposes, and the effect on the public health of the forthcoming shortage in the medical profession.

New Home for Bronx Hospital.—The Board of Directors of the Bronx Hospital and Dispensary have purchased the property on the southwest corner of Fulton Avenue and 169th Street, New York, consisting of three buildings and twelve city lots. Alterations will be started on the building immediately which will make them suitable for hospital and dispensary purposes. There will be accommodations for 100 patients in the hospital, which, it is believed, will be ready for occupancy by next fall.

Milk and Dairy Farm Exposition.—The Dairy-men's League held an exposition in the Grand Central Palace, New York City, during the week of May 20, which initiated an educational milk campaign. The point particularly emphasized was the necessity for using more milk if we are going to save our herds and dairy industry. Many addresses and demonstrations were given designed to show the value of milk as a food.

Medical Society Bans German Instruments.—The Iowa State Medical Society, at its annual meeting on May 11, passed resolutions declaring that it should be considered an evidence of pro-Germanism for any members of the society for the next fifty years to purchase instruments or appliances or other articles made in Germany.

Poor Milk Blamed for Increase in Infant Death Rate.—According to a recent Bulletin issued by Commissioner Copeland the infant death rate for the first five months of 1918 shows an increase of 5 per thousand over that of 1917. It is believed that the increased death rate is accounted for by a deterioration in the milk supply and by undernourishment. The present supply of milk distributed daily is 500,000 quarts under that of last

year. Dr. Copeland has ordered an inspection of all stores handling milk and of all the big milk companies.

Charitable Bequests.—By the will of the late Margaret L. Baugh of Tulip Hill Farm, near West Chester, Pa., a bequest of \$10,000 was made to the Presbyterian Hospital of Philadelphia and a bequest of \$5,000 to the Episcopal Hospital of the same city.

By the will of the late George W. Endriss of Philadelphia bequests were made as follows: Lankenau Hospital and Samaritan Hospital, each \$10,000; Episcopal Hospital and Hahnemann Hospital, each \$5,000; Pennsylvania Hospital, Howard Hospital, Medico-Chirurgical Hospital, Polyclinic Hospital, Jefferson Hospital, University Hospital, Presbyterian Hospital, Frankford Hospital, Roosevelt Hospital, Saint Luke's Hospital, Kensington Hospital for Women, Rush Hospital for Consumption, Free Consumptives' Hospital, Philadelphia Cancer Hospital, American Oncologic Hospital, Jewish Hospital, Philadelphia Home for Incurables, each \$1,000.

Examination for Laboratory Assistant in Bacteriology.—The New York State Civil Service Commission announces a competitive examination, open to men and women. Only applicants who have had a collegiate education, or its equivalent, who have satisfactorily completed a systematic course in bacteriology, and have had not less than three months' experience in a laboratory, will be accepted. Application forms must be filed with the Civil Service Commission at Albany before June 19, 1918.

Birth and Death Registration in the United States.—A Bulletin issued by the Census Bureau at Washington, on May 20, calls attention to the recent inclusion of Hawaii in the census area. Within this area now reside about 73 per cent. of the total population of the United States and Hawaii. Highly satisfactory progress in birth registration is reported for the last two years, although there are still a number of States in which adequate death registration prevails, but in which the registration of births has not yet reached a sufficiently close approximation to completeness to justify the acceptance of local records by the Census Bureau. The birth-registration area, as at present constituted, comprises 19 States: the six New England States, New York, Pennsylvania, Maryland, Virginia, North Carolina, Kentucky, Ohio, Indiana, Michigan, Wisconsin, Minnesota, Utah and Washington, and the District of Columbia. This area is estimated to contain about 51 per cent. of the total population of the country, as against about 31 per cent. when the collection of birth statistics was begun, a little more than two years ago, from an area comprising the six New England States, New York, Pennsylvania, Michigan, Minnesota and the District of Columbia. Until the matter is placed under Federal control or supervision it is not likely that reliable birth and death records, approximating completeness, will come into existence throughout the entire United States. Since the military registration of June 5, 1917, the desirability of maintaining such records has become apparent to all.

The Illegitimate Baby's Rights.—According to a report issued by the Children's Bureau of the United States Department of Agriculture, the Nor-

wegian laws are the first to acknowledge the rights of illegitimate children and the State's responsibility for seeing that every child, no matter what his parentage, has the nurture, protection, and education essential to his usefulness as a citizen. These laws make the State, instead of the mother, responsible for establishing paternity. The State holds both parents equally and continuously responsible for the illegitimate child. In commenting on this law the Children's Bureau says that the attitude which looks upon illegitimacy as a child welfare problem that must be solved for the sake of the child and of the State is exemplified by this Norwegian legislation. The bureau believes that the needs of the illegitimate child must be considered in the Children's Year campaign, and calls attention to the necessity of providing opportunity for normal development to the child of unmarried parents.

Errors Upon Certificates of Birth and Death.—The Bureau of Records of the Department of Health calls attention to the fact that it is called upon repeatedly to make correction of errors upon certificates of births and deaths filed by physicians. During 1917 over 1,000 applications were made for corrections as to name, date of birth, occupation, etc., which were either misstated by parents and relatives to the physician, or else were based on errors made by the physicians themselves. The value of these records depends a great deal upon the absence of alterations thereon. Very few physicians realize the extent of the service to which the certificates of birth on file at the Bureau of Records are put. During the year 1917 there were 108,296 free searches of the birth records for school and for mercantile purposes. It is urged upon the physicians of the city that care be taken in the writing of these certificates in order that the parents of the children may feel assured that a correct certificate has been filed, and to limit as far as possible the number of applications made daily to correct birth certificates.

Medical Society Elections.—The MISSOURI STATE MEDICAL ASSOCIATION, which met in Jefferson City, Mo., on May 8 and 9, elected the following officers: *President*, Dr. M. P. Overholser of Harrisonville; *Vice-Presidents*, Dr. J. D. Brullall of Salisbury, Dr. J. C. Matthews of Springfield, Dr. T. Guy Hetherlin of Louisiana, Dr. Scott P. Child of Kansas City, and Dr. John Isbell of Washington; *Secretary*, Dr. E. J. Goodwin of St. Louis; *Treasurer*, Dr. J. Frank Welch of Salisbury.

THE IOWA STATE MEDICAL SOCIETY, at its annual meeting, in Fort Dodge, on May 8, 9 and 10, elected the following officers: *President*, Dr. W. L. Allen of Davenport; *First Vice-President*, Dr. W. A. Rohlf of Waverly; *Second Vice-President*, Dr. Evan S. Evans of Grinnell; *Secretary*, Dr. T. B. Throckmorton of Des Moines; *Treasurer*, Dr. T. F. Dubigg of Des Moines.

THE IOWA MEDICAL WOMEN, at their annual meeting in Fort Dodge, on May 9, elected the following officers: *President*, Dr. Jeanette F. Throckmorton of Chariton; *First Vice-President*, Dr. Josephine W. Rust of Fort Dodge; *Second Vice-President*, Dr. Rosa Lowder of Maquoketta; *Third Vice-President*, Dr. Nellie Noble of Des Moines.

THE WOMEN'S MEDICAL SOCIETY OF NEW YORK STATE, at its annual meeting in Albany, on May 20, elected the following officers: *President*, Elizabeth

Burr Thelberg, M.D., Poughkeepsie; *First Vice-President*, Edith R. Hatch, M. D., Buffalo; *Second Vice-President*, Florence I. Staunton, M. D., Utica; *Third Vice-President*, Sarah J. McNutt, M.D., New York City; *Secretary*, Ethel D. Brown, M.D., New York City; *Treasurer*, Phoebe M. Van Voast, M.D., New York City.

Obituary Notes.—Dr. WILLIAM AUSTIN MACY of New York and Kings Park died suddenly of apoplexy, at the Kings Park Hospital, on May 21, aged 57 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1885, and was connected with the State Hospitals for the Insane for thirty-one years, having been assistant superintendent of the Ward's Island Hospital, superintendent of the Willard State Hospital, and superintendent of the Kings Park Hospital. He was a member of the American Psychiatric Society, the New York Academy of Medicine, and other medical organizations.

Dr. FRANK GROVE MCKLEVIN of Denver died of pneumonia in a local hospital in that city on April 22, aged 50 years. He was a graduate of the University of Pittsburgh Medical Department in 1892 and for many years was head of the medical staff of St. Anthony's Hospital.

Dr. GEORGE A. WILLIAMS of Brooklyn, N. Y., died of septic pneumonia following a long illness in the Bushwick Hospital on May 11, aged 63 years. He was graduated from the New York University Medical School in 1879. He was a member of the Associated Physicians of Long Island and one of the founders and directors of the Bushwick Hospital.

Dr. E. B. JACOBSON, resident physician at the Hebrew Hospital, Baltimore, died in that institution on May 16, aged 24 years.

Dr. SYLVESTER DEMAREST of Suffern, N. Y., a graduate of Bellevue Hospital Medical College, in 1885, died, following injuries received in an automobile accident, in the Paterson General Hospital, on May 10, aged 59 years.

Dr. WILLIAM P. McNALLY, a graduate of McGill University Medical Faculty, in 1897, died of pneumonia at his home in Bangor, Me., on May 2, aged 53 years.

Dr. ROGER MARTIN, a graduate of the College of Physicians and Surgeons, Baltimore, Md., in 1887, died at his home in Vulvan, W. Va., on May 7, aged 57 years.

Dr. FREDERICK CECIL SKINNER of Davenport, Iowa, who was taking a postgraduate course of study at the Post-Graduate Hospital and Medical College in New York City, died in that institution, following an operation, on May 11, aged 39 years. He was graduated from the Sioux City College of Medicine in 1898.

Dr. WILLIAM H. HOAG, a graduate of the College of Physicians and Surgeons, New York, in 1865, and a surgeon-major in the 134th New York Regiment during the Civil War, died at his home in Manhasset, L. I., May 13, aged 78 years.

Dr. CHARLES F. A. WALSH, a graduate of the Long Island College Hospital in 1895, died at his home in New York City on March 18, aged 55 years.

Dr. W. H. BRUSE, a retired physician of Mount Pleasant, Tenn., died from the effects of a dose of poison taken by mistake, on May 19, aged 83 years.

Correspondence.

COMMERCIAL MEDICINE.

TO THE EDITOR OF MEDICAL RECORD:

SIR:—There has been a deplorable tendency of late to vulgarize and cheapen medical standards. Reputable magazines and other periodicals open their pages to the disingenuous advertisements of charlatans in a manner they never did before, and while it is true that decent newspapers have excluded the vile sexual advertisements that formerly shocked public decency and worked incalculable harm to the ignorant, these have been superseded by quasi-scientific puffs and announcements, and the reclame of money-making projects. In at least one Sunday paper I found recently the glowing prospectus of a new organization, which seems also to be connected in some way with a supposedly ethical medical organization.

The apparent aim of this well-advertised concern is to afford superior medical advice by physicians who are supposed to be of exceeding merit, and apparently are not averse to being so classed. Like all things of the kind chiefly "run" by laymen, the methods of the correspondence school are utilized, and intending patients are requested to fill up blanks and detail their symptoms, although they may conveniently, after subscribing, consult directly with the medical authorities, who are said to be available. I have seen such a blank filled up by a wretched hypochondriac, and one can imagine the doubtful value of diagnoses made by the illuminati at headquarters who have such data alone upon which to proceed.

This kind of exploitation at once appears to present an affront to the more dignified members of an honorable profession, and naturally raises in the minds of the public a doubt as to their fitness. At a time when medical ethics existed in a more exalted degree than they apparently now do, it would be hard to find physicians in good standing who would be drawn into any such a money-making concern. The danger of the thing is that the names of well-known and prominent men appear to be used as bait, but the list of directors contains few, if any, names of physicians.

The cost of membership in this concern, we are informed, is low because of its humanitarian, character and national ideals; and the seeker for health need not necessarily consult his old friend, the family physician, but he may obtain "without any obligation" upon his part, a copy of an instructive pamphlet and afterward proceed to the fountain head of efficient medical knowledge.

ALLAN McLANE HAMILTON, M.D.

OUR LONDON LETTER

(From Our Own Correspondent.)

MEDICAL NEEDS OF THE ARMY—HONORS FOR GALLANTRY TO ARMY AND NAVY MEDICAL OFFICERS—REMUNERATION OF MEDICAL WOMEN—THE DRAIN OF TUBERCULOSIS.

LONDON, May 2, 1918.

AT the close of the first week of the great German offensive, the Army could congratulate itself upon having lost a far smaller number of medical officers

and far less medical plant and stores than would have been anticipated even by those familiar with the possibilities of a rapid retreat. It seemed a foregone conclusion that the hospitals could not be carried back in the time at the disposal of the retreating armies, while every one knew that, if those hospitals contained wounded, the medical officers and the personnel would stay by their charges, and the whole unit, building, men, material and stores would thus all fall into the hands of the enemy. So confidently was this anticipated, when some of the circumstances under which the Somme retreat was made became public property, that in several places the loss of hospitals and medical personnel was recorded not as a probable but as an accomplished tragedy. As a matter of fact, by wonderful organization, extraordinary endurance on the part of the patients, and great gallantry, the officers of the R.A.M.C. and their men succeeded in carrying off from the invaded area most of their patients and most of their material, and have themselves escaped from the deadly ordeal of imprisonment in Germany. The saving of the medical personnel is a matter of great importance in view of the distinct shortage of medical men which now exists in many parts of the United Kingdom. For a long time this shortage was more apparent than real. Localities of under 10,000 which had always been used to the service of seven or eight doctors thought themselves very badly treated fifteen months ago when the activity of the Central Medical War Committee reduced those seven or eight doctors to five or six; but within the last six months they have found that they can get on with three or four. On the other hand, the medical men themselves find that with the enhanced value of time and with distinct cooperation on the part of the patients in its saving, they can do more work and do it in a more systematic manner. Undoubtedly in most populous centers and in all great rural districts where the distances from door to door are great, the medical men are very hard worked, but the breaking point has not been reached at many places. None the less, there no longer remains the least superfluity of medical men in home practice, and therefore it is a matter of great congratulation that no sudden draft has to be made for the sake of the Army upon those that remain at home.

The official *Gazette* now contains the details of the heroic actions with the British Navy and Army which have gained for no less than ninety-six medical men various recognitions in the form of decorations. Ten have received the Distinguished Service Order (D.S.O.), and two holders of that order, which ranks second only to the Victoria Cross, have gained a bar to the medal, in other words, have earned the D.S.O. twice. Seventy-four officers have received the Military Cross (M.C.) for deeds whose bravery or utility is in many cases undistinguishable from the similar qualities which have earned their colleagues the D.S.O.; nine officers have received a bar to their crosses, and one has received a second bar, showing that he has been awarded the cross three times. The *Gazette* indicates with what complete unanimity the British Colonial medical men have volunteered for military duty, for eleven of these decorated officers belong to the Canadian Medical Corps, ten to the Austro-

lian Medical Corps, four to the New Zealand Medical Corps and one to the South African Medical Corps, chance not having taken the African contingents much into the actual fighting wherein the distinctions were gained.

Those in charge of the economic interests of the country are just now much exercised as to the question of women's remuneration and the value of women's service, because in so many places women are doing men's work and doing it at rates of pay which it may not be possible to maintain after the war. The position of medical women becomes very interesting from that point of view for they represent the intellectual flower of self-supporting women, while they are also the class of women workers who understand best how to realize the value of cooperation. When women first aspired to join the medical profession in Great Britain there was a great deal of opposition in that profession of worthy and unworthy sort. I do not refer to views based either upon the early Victorian estimate of woman's sphere or upon fears, however legitimate, of loss of employment by men through successful female rivalry. There were general and genuine apprehensions that in the hard and often terrible life of medicine women might be found physically or temperamentally wanting. Gradually these apprehensions disappeared as women won their way surely into the medical profession, but it should be pointed out that their difficulty in many instances in obtaining posts, after the way to qualification had been opened to them, was not necessarily the unenlightened result of old prejudices. As often happens with an innovation, the new thing arrived before its environment was ready for it. The people who built hospitals and institutions had not provided for young resident officers of opposite sexes either in sleeping or lavatory accommodation. When boards of hospitals chose among the applicants the respectably qualified man rather than the brilliantly qualified woman, it was not so much that they felt that to appoint the woman would be an experiment as that to choose the female would have entailed upon them a certain amount of trouble because of the necessary alteration in the domestic accommodation at their disposal.

The war has done away with all such difficulties. When a Minister with a wave of his hand can turn half a dozen hotels and as many clubs into Government bureaus no hospital committee would hesitate about the alteration of a few partitions and the addition of a few drainage pipes. Women are now welcomed in the whole institutional sphere of medicine, and at salaries equal to, or greater than, those previously enjoyed by the men. This is as it should be, for from the beginning as women became employed in medical posts they were found to do their work as well as men. The academic work done by the women is and has always been admirable, but many of them graduated at the University of London at the very time when the high standards of that university had betrayed it into making its examinations very unpractical, so unpractical that the General Medical Council called attention to the fact. Some of the early women doctors, whose training had been of this literary and cloistered sort, obviously felt their responsibilities so keenly as somewhat to unfit them for the

more ordinary routine, and in one case at least a dramatic tragedy brought this home to the authorities of a great London institution. But all this is now altered and it seems to everybody that women can take their place by the side of men in the medical profession so adequately that no question should arise as to their receiving the same emoluments. Yet the question has arisen, and very acutely, in a good many places. The British Medical Association, constituting itself roughly into a trades union, has decided that the holders of certain posts, rewarded by salaries drawn partly from the Local Government Board and partly from local rates, should not accept less than a certain figure. For the most part the members of the association accepted the suggestions of the association, for considerable pressure can be brought to bear upon medical men who do otherwise. The lay authorities finding their proffered terms rejected by men made resolute attempts to lower the male price by selecting female candidates willing to take abated salaries. Very promptly the women combined and refused to have anything to do with such tactics, and their combinations have been generally successful. But the sacrifice has all been on the women's side, because most of the authorities, failing to secure male labor at a lower price than female labor, continued to appoint males. Now in many instances the abated salaries would have been adequate for single women and the posts would have formed admirable introductions later to private practice.

It is fairly certain that women will continue to obtain after the war such posts as they now hold, if and when they apply for them, and in the same proportion as they are obtained by men, where the man and the woman are, on the face of things, equally suitable candidates. If the posts that can thus be described are still comparatively few, the number of women on a medical register, though increasing so rapidly, is still but a fraction of the number of men, so that numerical justice will be maintained. The position of medical women, in establishing the principle that for work of equal value equal wages should be paid to the two sexes, is much envied by women in the industrial world; they use the more fortunate portion of the medical women as a constant argument for the advance in commercial wages, somewhat forgetting that the medical woman is a person of very special training. A soprano gets as much as a baritone, a female dancer is better paid than a male dancer; their work is still more specialized than the work of medical women, and the absurdity of using their rates of pay as an argument in connection with commercial wages is obvious. But though it is obvious it is not more truly an absurdity than to found a theory about the wages of mill hands on the fact that a female medical inspector of schools is paid the same salary as a male inspector and has been able to enforce such payment to herself.

At the time when the principle of national insurance was being freely discussed in Parliament one of the provisions in Mr. Lloyd George's bill which met with general favor was that in which he proposed to devote a special part of the money raised to the prevention, systematic treatment, and cure of tuberculosis. Any organized method of

dealing with the disease which exacts such a regular toll in death and disability from the British nation was certain to receive a warm welcome from legislators, while the value of the anti-tuberculosis work projected was seen to be further enhanced by the amount of time otherwise spent by general practitioners in struggling with the disease which would now be set free for other medical purposes. The argument to the general practitioner ran as follows: "A great deal of your time is spent in the treatment of chronic tuberculous cases, which reach your hands because they are on the books of certain clubs or medical aid associations. These patients require from you supervision and drugs, and every one which you have on your books under the present system is a dead pecuniary loss. Under the National Insurance Scheme these patients will be removed from your lists and you will be spared the drain upon your time and pocket. This must be regarded as a pecuniary benefit." The medical profession did not as a whole look at the matter quite from Mr. Lloyd George's point of view, nor did those who had real medical experience of the care of the sick poor in Great Britain feel very sanguine about any abatement in tuberculosis following upon the National Insurance Scheme which would be quicker than that abatement which had already taken place and had been taking place for over a decade in every division of the United Kingdom except Ireland.

On the whole, the pessimists have been proved to be wrong; the drain of tuberculosis upon the nation is less steady and less terrifying, and National Insurance must be given some credit. Few or none of the results of the National Insurance Act can be taken as evidence for or against the value of its operation, since before the effect of the new legislation could really be felt by the nation at large the war broke out and the medical organization of the act had to give way to the military and social needs of the country. But undoubtedly the act has strengthened in many directions the hands of those whose work especially lies in the prevention of tuberculosis. It is true that difficulties are now being experienced in all parts of the country in providing sanatorium and institutional accommodation for tuberculous subjects whether among the population at home or among the returned discharged soldiers and sailors, and in London especially the institutional accommodation has proved far too scanty. A long waiting list of cases medically recommended for institutional treatment was awaiting admission to sanatoriums over a year ago, and this list has steadily grown. The London Insurance Committee is at times acutely embarrassed to find shelter for discharged sailors and soldiers, and the number of applications for sanatorium benefit received by the committee during the first three months of the present year has been very large. But none the less the story, though it reads dismally, is a hopeful one. There were more cases before National Insurance formed the machinery to detect the incidence and correct the mischief in early patients. The very troubles of administering the tuberculosis benefit advertise the existence of the disease and form a call upon the public which is now being responded to. Publicity here is doing good educational work.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

RECONSTRUCTING THE REGAINED REGIONS—SCARCITY OF SURGEONS—MEDICAL SCHOOLS ON THE BATTLE LINE.

PARIS, April 15, 1918.

THE American Red Cross has a large scheme for developing its work in the liberated area of France. Mr. Edward Eyre Hunt has returned from a tour of the six districts in which his Red Cross Bureau of Reconstruction has established warehouses, etc., and emphasized the importance of bringing back the liberated regions to effective fruitfulness as France's granary. One-quarter of the wheat produced in France before the war was raised on the five million acres of land which make up the invaded departments and 87 per cent. of the national crop of sugar beets—all this in addition to industrial productivity. Of these five million acres, nearly a million have been reconquered. The more recent advances of the Allies have freed for cultivation more than 250,000 acres behind the formal battle front. The food problem is both a social and a military one, so it is important that we bring back the farmer to the land, giving him the indispensable shelter and tools.

Some of us have an exaggerated idea of the amount of damage done to the land which lies between Paris and the present front. While there are certain stretches which it would take months of intensive labor to reclaim, and parts, like the battlefield of the Somme and Vimy Ridge, which it will take generations to reclaim, such regions are the exception. But the villages where the peasants formerly lived are practically annihilated. Roofs must be patched, walls re-erected, windows and window-frames put in, and barns built before the peasant can begin to use the land to the utmost. This work is being done in the devastated regions by military labor and, far enough back of the lines, by the labor of prisoners, and, in sound of the big guns, by members of the Society of Friends who have elected that form of war service. These various forms of reconstruction can be seen going full blast throughout the country round Roye and Noyon. Besides patching roofs, it is often necessary to mend stables. In some cases the farmer comes back to the stable, where it takes less work to restore this than to renew the utterly destroyed farmhouse. Where the devastation has been worst portable houses constructed in the Jura by the Friends or furnished by the French Ministry of the Interior and set up on or near the ground that is to be cultivated, are proving satisfactory. The two difficulties involved in this work of providing shelter for the returning farmers of the liberated regions are the scarcity of labor and of food.

Up to date the main work of the Red Cross Bureau of Reconstruction and Relief has been to devise an organization to distribute relief supplies in kind. We have used as our agents existing French or American relief organizations. Our original warehouses have been located where the hauls are short and local deliveries have been made by camion. More and more we have been

able to cooperate with the French "œuvres," admirable field organizations which apply to us for clothing, household goods, bedding, furniture, farm implements, etc. We have storehouses at Arras, Amiens, Ham, Neale, Soissons, Noyon, and Nancy. We have distributed building material to "œuvres" engaged in reconstruction; French charities and the French army have used our tar paper, our timber, our windows, our window-glass, and our hardware, and through them we have distributed rabbits, goats, and other small live-stock. Up to January 1 we had distributed among other things, 27,548 meters of clothing material, beds and bedding, thousands of pairs of shoes and stockings, stoves by the hundred, agricultural implements and kitchen utensils by the thousand.

In time of peace France had a total of about 15,000 doctors, few enough for a population of 35,000,000; but it is not an easy matter to become a doctor in France; at a minimum it requires eight years to secure the degree after having passed the bachelorat and during this time the student must be supported in a fashion suited to the social position attached to his profession, which is high, and he rarely is ready to open an office prior to the age of 30. So it is only a certain class that enter the profession and they must be willing to sacrifice their younger years and the ranks are never overcrowded. This explains why during the greatest of all wars France has suffered for lack of medical help, and foreigners like myself who have taken the medical degree in France, have been freely welcomed and appointed to important posts. Many foreigners without the French degree, but possessed of credentials satisfactory to the authorities, have been incorporated into the service, but more than this: Early in the campaign a call was made upon all medical students, who have been distributed behind the front and at base hospitals as aids to the doctors and surgeons in charge and have not only rendered valuable service, but have in many instances surrendered life or limb upon the field, in the fearless performance of their duties.

Recently an innovation has been inaugurated because of the prolongation of the war and arrangements have been completed to carry on three medical schools behind the lines, near the front, where these students can after a fashion prosecute their studies and not be unduly delayed in securing their degrees. The courses of instruction are mapped out and at fixed periods the students meet given professors at the centers fixed for instruction and examination along the prescribed lines; so it is that again necessity becomes the mother of invention; but it goes without saying that the training these students are daily subjected to, mental, moral, and physical, is calculated to make better doctors than any didactic course that could be imagined.

146 AVENUE DES CHAMPS ELYSÉES.

Camptocormia.—This new affection has been made the subject of a French thesis. Souques, who first described it, terms it a vicious attitude; it is a permanent forward flexion of the trunk; the head being thrown back in order to see. The condition has no pathology—in other words, is hysterical.—*Journal de Médecine et de Chirurgie Pratiques.*

1. Traumatic Shock. W. T. Porter.
2. The Anatomy and Physiology of the Respiratory Tract. Frank F. D. Reckord.
3. A Portable Respiration Apparatus for Clinical Use. Francis G. Benedict.

1. **Traumatic Shock.**—W. T. Porter enumerates the hypotheses usually given as the cause of shock. (1) *Exhaustion of the vasomotor center*—this, he says is impossible because the center does not become exhausted but still reacts to the stimulation of the depressor nerve. (2) *Excitation of sensory nerves*—the writer points out that the sensory nerves in normal animals may be strongly stimulated for many hours without producing a noteworthy fall in the blood pressure; a condition roughly resembling shock may follow injury to a nerve during operation, but this condition is not shock but a prolonged inhibition of the heart. The explanation of this may be that the patient is in a certain state for which Porter proposes the name "sensitization," a conception which is new and which he bases on the following experimental evidence: (a) In 50 per cent. of dogs given morphine and curare, ligation of the ramus descendens of the left coronary artery produced fatal fibrillation of the heart, whereas fibrillation very rarely occurred when ether alone was used. (b) In a rat to which morphine and curare were given, gently lifting the sciatic nerve on a thread caused inhibition of the heart, lasting over half an hour. (c) In a tortoise heart, a stimulus which ordinarily caused a tonus contraction lasting thirty seconds, caused in this case a contraction lasting sixty-four minutes. The writer has no experimental evidence as yet of such sensitization of the arteries, although there is some clinical evidence of prolonged contraction or relaxation of the blood vessels following stimuli ordinarily uneventful. (3) *Hydrostatic fall in blood pressure*—Porter points out that a simple hydrostatic fall in blood pressure is not shock, but should the low pressure continue long enough to impair the nutrition of the vascular apparatus shock may ensue. (4) *Vibration injuries*—these may cause shock when the vibration shakes the vasomotor cells until their function is impaired. (5) *Direct wounds of the vasomotor apparatus*—if in the abdomen, hydrostatic shock may follow. (6) *Hemorrhage*—Porter points out that hemorrhage is not usually a cause of shock, as in the present war, for instance, it almost always happens that there are men who have lost more blood than the shock cases. The loss of a small quantity of blood may be a serious matter, however, if the blood pressure is near the critical level, which is the point below which the blood pressure will not usually rise again without assistance. In the study and treatment of shock, it is of first importance to remember that if the blood pressure just touches this critical level, a difference of ten millimeters may be the difference between life and death; that procedures which at ordinary blood pressures are not harmful may kill the patient at the critical level; and that remedies that raise the blood pressure but ten or fifteen millimeters will save the patient when this rise carries the pressure from just below to just above the critical level. Frequent readings of the blood pressure until the patient is out of danger are of the greatest importance. The diastolic and not the systolic pressure should be employed. Porter found that the injection of a small quantity of neutral olive oil in the jugular vein resulted in a fall of the blood pressure and other symptoms of traumatic shock, or—in other words—that shock is frequently caused by fat embolism. He also found that the diastolic pressure could be increased by allowing an animal to breathe in an atmosphere rich in carbon dioxide, thereby producing strong respiratory movements of the diaphragm. He has applied the method with success in the treatment of wounded soldiers. The general treatment employed by him was as follows: The patient was carried from the ambulance to the shock room, a room adjoining the operating room, was not washed but placed at once on an operating table, inclined so that the feet were 30 cm.

higher than the head. An electric heater was then placed between the blankets and the body. The diastolic pressure was taken every fifteen minutes. Where indicated, injections of warm normal saline solution were made into a vein; adrenalin was added to the solution in grave cases. Carbon dioxide respiration was used. When the patient's condition justified operation the clothing was cut away about the wound and the area disinfected and neighboring regions covered with sterile cloths. Patient was then moved into the operating room and the operation performed, if possible, under local anesthesia. Under these methods four-fifths of the patients recovered.

5. Relation of Industrial Hygiene to General Practice. —Louis I. Harris estimates the industrial population of New York State at 3,000,000 and points out that less than 100 factories and mercantile establishments out of a total of more than 78,000 had any substantial welfare organization at as recent a date as October, 1917. By medical welfare work is meant a system of organization which has in view the periodic medical examination of employees and the provision of medical and surgical care to prevent serious illness, as well as to treat those who may be injured. Labor turnover, or the constant change of employees—which is economically wasteful—can be largely prevented by medical welfare work, as was proved by Dr. Marquis, who was able to reduce it from 56 to something like 14 per cent. in one year at the Ford Automobile Company's works. The proper function of a doctor in a large industrial establishment is to serve as a staff or advisory officer with a view to eliminating conditions detrimental to health. He must be qualified to examine every branch of the industry, know the composition and nature of the chemicals employed and their possible effects upon health, and understand ventilation, lighting, temperature, conditions which bring about muscular, nervous, and mental fatigue, etc., which all constitute the true field of industrial hygienic study. The writer goes on to cite cases of lead poisoning and other occupational disease, which could be largely prevented if working conditions were carefully studied by a competent physician. Harris adds a plea for a larger measure of respect for industrial hygiene; it is time that it was given a hearing in the schools of medicine and that something was done to indicate its place as another link between medical science and practitioners in the effort to secure human welfare. He believes that, speaking generally, physicians of New York City have been slow to appreciate the progress of industrial hygiene. A certain number of medical adventurers, however, have formed a number of medical organizations for commercial exploitation under pretense of offering their services as industrial hygienic supervisors. Believing that health insurance, when it becomes effective, will stimulate interest in this work, Harris points out that the time is ripe for the organization of reputable medical practitioners into groups who will establish medical service stations in factory districts and thus serve the needs of small manufacturing establishments, who could not afford to employ independent medical officers. Such officers should be prepared to give the benefit of their knowledge of sanitary engineering to owners of factories and act as advisers for the prevention of disease and not merely as therapeutists and surgeons. The stations should also receive and treat medically and surgically all cases requiring treatment, and should respond to emergency calls.

2. Nurses and the War.—Philip King Brown suggests that the present shortage of nurses should be met in somewhat the same way as the shortage of officers in the army has been, i.e. by intensive training. It would certainly be better, he states, to have an adequate supply of fairly trained nurses than to have to fall back on those who are willing to serve but who have had no training. He gives a review of the practical educational opportunities offered to nurses in Californian hospitals and points out that among the seventy-two schools the nursing of tuberculous patients is taught only in thirteen, that of mental cases in four, practical public health in one only, where it is an elective subject, and the nursing of occupational diseases in none; moreover, an undue importance is attached to surgical work. Brown objects, therefore, that the present system of training lacks balance, is wholly inadequate in many departments in most hospitals, is too apt to be largely surgical, and fails to cover a number of medical conditions in which special training is necessary. He is also of the opinion that training schools undertake too much academic work, and that since the special lines of nursing are best prepared for after graduation, the three-year course of preparation for them is too long. He considers the relative cost of training in time and money in the nursing and other professions open to women and points out that nursing is the only one in which students are given room and board free of charge and, instead of paying for their instruction, are paid for their services during training. The writer summarizes the situation as follows: 1. The 7,000 already enlisted Red Cross nurses have created a noticeable shortage, although they constitute only 6 to 8 per cent. of the supposed total of from 80,000 to 90,000 registered nurses. 2. The need expressed by General Gorgas for 5,000 nurses within two and a half months and a balance of 35,000 within the year cannot be met by volunteers, and it is doubtful if it could be dealt with by conscription in fairness to the community and the nurses themselves. 3. No plan for an adequate supply of nurses has been seriously advocated, although the curtailing of the three-year course for certain well-educated women, and the provision of special preliminary training enabling others who take it to cut down the three years, are steps in the right direction. 4. The time for a complete change in the nursing situation is at hand, and the change should be made along the lines of (a) more fitting preliminary training in subjects that hospitals cannot teach to advantage; (b) the cutting of the course in hospitals down to four terms of three months each, for which the young women pay, and during which time they receive more personal supervision from trained teachers, and (c) the abolishing of the boarding of nurses in the interests of getting a better class of women, and lessening the expense of operating hospitals.

3. Cerebrospinal Fever: Notes on 92 Consecutive Cases.—Captain W. H. W. Attlee gives a summary of the results of treatment in a series of cases which occurred among soldiers between 19 and 48 years of age. Only two patients came from any one unit, and they were from different companies in the battalion. The average day of disease upon admission was the fourth. All were treated with Lister or Pasteur serum, given intrathecally; in one case, which resulted fatally, it was administered intravenously as well. As the Pasteur serum did not agglutinate with any of the strains of meningococci, Lister serum was given at first until the supply ran short. In all cases but six the meningococcus was seen in the cerebrospinal fluid and in most cases it was cultivated. In the six negative cases the fluid was turbid and contained many polymorphonuclears, and one of these patients died with the usual postmortem appearances in the meninges of cerebrospinal fever. Of thirty-three cases treated with Lister serum eighteen recovered and fifteen died. Of the recoveries two were completely deaf when evacuated, and one was completely deaf in one ear. Fifty-two cases were treated with Pasteur serum; of this number thirty-three recovered and nineteen died. There was no permanent disability among those who recovered. Seven cases were treated with Lister and Pasteur serums combined; of these cases four received first Lister and afterwards Pasteur serum, and all died; the other three who recovered, began with Pasteur serum and afterwards, owing to a shortage in the supply, were given Lister serum. Of the fifty-four patients who recovered, twenty-four were unconscious or delirious upon admission and thirty-three were sensible. Of the thirty-eight who died twenty-three were unconscious or delirious upon admission. In every case the neck was definitely stiff, and Kernig's sign was definitely present at some time during the illness in all those who were not comatose or moribund. Twelve cases had rashes, six recovering; in twenty-two one or more cranial nerves were affected, trismus being definitely noted in sixteen; and nystagmus was common. Serum arthritis was common, and urticarial and erythematous rashes frequently noted. Headache was the only constant symptom and stiffness of the neck was the only sign of real help in diagnosis. The temperature and pulse were variable and were valueless as signs. As a practical working rule the author came to the conclusion that a man who is ill, complaining of acute headache of sudden origin, without any definite physical signs other than neck stiffness, should be suspected of having cerebrospinal fever and should be punctured without delay. From these findings the author reached the following conclusions: (1) The disease can be only slightly infectious; at any rate in the field. (2) Early diagnosis would be more common if it were made a routine to test for neck stiffness in all acute illnesses with headache. (3) Early treatment seems to be of the utmost importance. This series of cases, in which treatment was begun on the average on the fourth day of the disease, compares very unfavorably with other series in which treatment was begun, in the majority of cases, during the first forty-eight hours. (4) Serum does seem to have some effect. The differences in the mortality in this series cannot be explained altogether by the possibility of there having been more mild cases in the Pasteur series than in the Lister. (He adds that since the above notes were written five more cases have been treated with Pasteur with four recoveries and one death.)

6. Acute Metatarsal Overstrain (Foot-swelling).—A Rocyn Jones describes the case of a soldier in which a provisional diagnosis of trench feet was made. An x-ray examination, however, showed fracture of the second metatarsal bone in each foot. He points out that marching fractures seldom occur in both feet and gives the figures of Nion, who found that out of 575 cases in two only were both the second metatarsals affected, in one both the third, and in one the second and third. Rarely are there two fractures in the same foot, either, and in Nion's series the second and third metatarsals were broken only in four cases, and the second and fourth in one case. Acute metatarsal overstrain is practically confined to the three middle metatarsals and Nion gives the proportions of 112:98:17 for the second, third, and fourth metatarsal, respectively. Rocyn Jones points out that the second metatarsal bone is the one most subject to variation; it may be the strongest next to the first metatarsal, or it may be the weakest. The third is always a weak bone. The frequency of fracture of these bones is due to their commonly slender length, their fixity, their direct forward projection, their line in the transmission line of body weight, and the part they play in the leverage action of the foot. The development of symptoms, as a rule, is gradual during a march, and there is rarely any account of accident. The pain is localized to the metatarsus, and by running the fingers along the bony shafts a very sensitive spot will be found in one of them. If a fracture occurs, discoloration of the skin due to extravasation of blood may be present and possibly crepitus elicited. Swelling of the foot is usually a prominent feature. The diagnosis can only be definitely established by the x-ray. If there is no fracture periostitis may be present and is shown in the skiagram by vagueness and irregularity of outline. The condition occurs more frequently in troops from lowland than from mountainous districts, for hill climbing tends to strengthen the metatarsus and pedal muscles, and possibly to promote a better power in dorsiflexing the foot. *Treatment:* Complete rest off the feet for four weeks, and the application of massage and hot air. The heating chamber should be at a temperature of 300° Fahr., and the limb well protected by wool and flannel bandages. Treatment should occupy from thirty to forty minutes daily. As an alternative treatment passive hyperemia may be adopted. A Martin's bandage is applied round the leg just above the ankle, so as partly to obstruct the venous flow from the foot. This treatment should be applied first for an hour daily and gradually extended to several hours. At the end of one month or less in the case of periostitis the patient is allowed to get on his feet gradually, and ten days later, if there is no pain or swelling, to walk freely. In the case of fracture a transverse "football" bar may be worn for a few weeks and then discarded. Care should be taken that a properly fitting boot is provided.

1. The Selection of Abdominal Cases for Operation, With Reference to a Series of 200 Operations.—Colonel

Owen Richards points out that the percentage of patients who survive operation is no real index of the value of treatment. The real successes are the cases in which a fatal injury is found and cured; the failures are those in which a patient is wrongly classed as moribund when operation would have saved his life and those in which a penetrating wound of the abdomen is not recognized as such until it is too late. Failures due to bad surgery, he states, are relatively rare, for the general level of surgical skill in the clearing stations is a high one. The difficulty lies rather in the selection of cases. Though the series reported is small, the writer believes that it represents a fair average both as regards results and conditions, and his experience has led him to the following conclusions: (1) The decision as to whether a man wounded in the abdomen should be operated on or not is usually based on the time which has elapsed since the injury and the rate and character of the pulse. (2) Of the patients who survive operation performed in the first twelve hours a high proportion will have had their lives saved by it, and this is true in a lesser degree of those operated on in the second twelve hours. After this time most of those who survive operation are those whose injuries were not originally fatal. (3) Men with a pulse of 120 or over have less than half the chance of survival of men with a lower pulse. (4) Recently wounded men, with a rapid pulse, should nevertheless be operated on, provided that their condition is as good as it is ever likely to be, that they have a reasonable prospect of surviving the actual operation, and that the time taken does not prevent the proper treatment of other wounded.

Familial Hydrocephalus; a Contribution to the Determination of Sex.—W. Hannes publishes the case history of a female who gave birth to a hydrocephalic boy, having previously been delivered of a hydrocephalic male and a normal female child. This case, compared with other similar reported cases, leads the writer to suspect malformation of certain ova, and precisely male ova. In point of fact, the mother of the woman in question had given birth to three normal daughters and one hydrocephalic boy. The writer therefore believes in the theory of preformation of sex, each ovum being already of a given sex before fecundation has taken place. He recalls the importance of the study of this question at a time when so many men are being killed in war.

The Treatment of Suppurating Joint Collections.—C. Ritter considers that puncture, followed by immobilization in a plaster cast, is the best treatment. At the beginning the cast must not be applied too snugly, but later it should be applied as exactly as possible to the limb. The plaster is changed three to four times with a week's interval. Even after recovery has taken place it is well to continue the wearing of the cast in order to avoid edema and hyarthrosis resulting from the distension of the synovial. The danger of contractures and ankyloses has been overrated, and for this reason a prolonged application of the cast is advised.

Orthostatic Purpura.—W. Schultz has studied a patient offering this affection, likewise the literature of the subject. Schultz's case is to be attributed to a fundamental weakness of the vessels which allowed the blood to transude under the influence of stasis. Such cases have often been likened to hereditary or latent tuberculosis. It is possible that anaphylaxis plays a part in these orthostatic purpuras, and they are, for that matter, frequently accompanied by articular manifestations.

A Working Claw, Movable at Will (Spitzgreifhand).—F. Sauerbruch enters into a long, tiresome discussion on the prothesis of amputated arms and offers a description of an artificial member he has devised. The device is very complicated, and to the American mind would appear rather ridiculous, although the writer decries the models made in the United States.

The Tenor of Infectious Bacteria on Penetrating Missiles.—E. Wetzel has noted that there is a relative sterility of these projectiles. The writer found staphylococci on one bit of exploded shell out of a total of 28 cases examined, and on two rifle bullets out of a total of five cases examined. Two shrapnel bullets were found to be sterile. Neither the depth, site nor type of wound resulting appeared to have any influence on the degree of septicity, and the writer concludes that missiles may be removed through the track itself, without resorting to incision.

March 7, 1918.

Serologic and Serotherapeutic Studies on Gas Edema.—W. Kolle, L. Sachs, and W. Georgé point out that the varied pathogenic agents of this disease require the use of a polyvalent serum. The horse serum employed by the writers agglutinates and splits up the complement in a very complete fashion for the different microbe species, both the motile putrefactive types and the nonputrefactive types. The writers obtained their serum by injecting both living and dead cultures, thus freeing both the microbe and histogenous toxins. Experiments showed that the administration of this serum at the same time as an injection of toxins in the guinea pig preserves the animal, particularly against intoxication. In comparison to simple horse serum, the polyvalent antigas edema serum possesses an action twice as strong. Antidiphtheritic serum is also far less efficacious and the writers even claim that in certain conditions it is favorable to the extension of the process. The curative action of the serum is even more manifest when injected in doses several times lethal in toxin. A dose of toxin eight times lethal can be neutralized by the specific serum when this is injected three to four hours after the introduction of the toxins. The writers conclude that in man the specific serum should be used as early as possible in all cases of declared gas edema, in the dose of 150 to 200 c.c. As a prophylactic measure it probably has no value.

A New Technique for Discovering the Bacillus of Tuberculosis in the Sputum.—K. Brauer advises a technique which he considers superior to that of antiformin. The simplified technique is as follows: The sputum is diluted with an equal quantity of water. Next a few drops are added and the liquid heated. Then add ½ c.c. of a 10 per cent. solution of alumin sulphate, shake and heat again. Filter and examine the filtrate after straining it with the customary reagents. The principle of the method is that there is formation of a precipitate which carries the bacillus into the deposit.

The Action of the Spoken Word on the Width of the Pupil.—Van Ravenswaaij states that the following can cause dilatation of the pupil: pain, dyspnea, loss of consciousness and drugs like atropine, duboisine, and cocaine. As far as he knows no one has ever described an acoustic pupillary reflex. The experiment is carried out as follows: The illumination must be constant and the subject directed to fix his gaze on a distant point. A third person, at a distance of several meters, calls out various words with certain pauses between. Almost immediately upon the word there is a brief dilatation of the pupil. The explanation is thought by the author to be as follows: It is especially the spoken word which calls up ideas that produce the phenomenon, and naturally varies with the individual. With a soldier words like "march," and similar words of command, are most efficacious. We have here doubtless a cortical reflex which is somehow projected along the sympathetic fibers. We appear to have here a new method for the detection of simulated deafness.

Dementia Paralytica in a Child.—Dupré's case began at the age of 9 and was first seen four years later. The evolution was therefore slow and growth and development hindered. Simple dementia developed. The case is instructive because free from components seen in the adults—alcohol, etc.—*Archives méd. Belges.*

One Hundred and Twelfth Annual Meeting Held at Albany, May 20-24, 1918.

(Special Report to the MEDICAL RECORD.)

(Continued from page 922.)

SECTION ON OBSTETRICS AND GYNECOLOGY.

First Day—Tuesday, May 21.

DR. JAMES KNIGHT QUIGLEY IN THE CHAIR.

Sterility.—Dr. GEORGE MERRILL GELSER of Rochester read this paper, in which he stated that sterility was of three types: (1) That in which it could be attributed to the male. (2) That in which it could be attributed to the female. (3) A type in which both male and female were normal, but in which the sterility was due to a hemolytic action in the bloods of the male and female. Sterility might be due to obstruction in the generative tract of the male, to obstruction in the generative tract of the female, to absence of spermatozoa, to absence or deficiency in the development of the ovum, to alterations in the female secretions, or to hemolytic action between the secretions of the male and female. The obstruction in the male generative tract might be due to trauma or tuberculosis, but in the vast majority of cases it was due to gonorrheal infection. Such obstruction might be relieved by operation, such as vasectomy, either with the vas or epididymis of the same side or the opposite side. Obstruction of the urethra might be relieved by dilatation or operation. For deficient spermatogenesis glandular therapy together with regulation of the mode of life and improvement of the general health might be of benefit. Hyperacidity of the vaginal secretions might be relieved by alkaline douches or alkalines by the mouth and by depletion to relieve pelvic congestion. Cervical obstruction might be treated by dilatation, plastic operation, or by direct uterine insemination. Cervical infection with alteration of the cervical secretions might be treated by repeated disinfection combined with a plastic operation, removing the diseased cervical mucous membrane, or by direct uterine insemination. In either of the foregoing instances in which spermatozoa were weak, or the vaginal and cervical secretions hostile or the cervical canal obstructed, direct uterine insemination gave promise of being the most efficient procedure. This procedure should be carried out either a few days before or directly after menstruation. The technique to be followed consisted in instructing the husband to wash the penis and boil the condom and then to keep the condom with the contained semen at body temperature and call at the physician's office immediately. Then with the woman in the Simms position and with a special syringe or catheter a small amount of semen was injected into the uterus one and three-quarters to two inches. Then the woman should be kept lying down fifteen or twenty minutes. When the uterus was definitely abnormal a gentle curettage or occasionally a plastic operation of the tubes might be indicated, but one should not undertake such an operation until all other etiological factors had been eliminated. In cases in which the ovary or uterus were undeveloped, glandular therapy might be of benefit. Extract of corpus luteum had given but little success in the hands of the author. Thyroid extract occasionally helped. The facts should be emphasized that sterility was more often attributable to the male than to the female; that it was necessary to make a painstaking examination of both the gross and the minor alterations in the female generative organs, and that direct uterine insemination was of value. Glandular therapy might be used for cases with weak spermatozoa or underdevelopment.

Dr. EDWARD J. ILL of Newark, N. J., expressed the opinion that a great deal in reference to sterility must of necessity remain theoretical, but that if we would

follow the veterinarians, especially the breeder of hogs, we might learn a great deal. They seemed to know a great deal more about sterility in animals than we knew about our own race. A simple examination of the semen was not always satisfactory. He quite agreed with the essayist that the fault usually lay with the male and breeders would tell us that the same thing was true of animals.

Dr. W. B. STONE of Schenectady cited a case of pregnancy with the birth of a normal child that took place in a mother of arrested development. She had the development of a child of twelve years. She was married and at the age of 22 there was no development of the external or the internal genitals. She gave birth to a normal child without having been able to have normal intercourse. When she was six months pregnant the external genitals began to develop, and she had a confinement which was practically normal. This showed that when the spermatozoa were normal they had great power of motion and could overcome great physical obstruction. Sterility in many cases was a much deeper and broader thing than was generally recognized; it was in some cases a biological incompatibility of the male and female secretions. The reader of the paper had spoken of a hemolytic action of the blood of the husband and wife. The way to do was to test the compatibility of the blood just as though one were testing the bloods for a transfusion. The speaker had tested five or six cases in which there was sterility, with no history of gonorrhea and no obstruction in the generative tract of either the male or the female, and there was a marked hemolysis of the red cells. The red cells of the husband would dissolve and agglutinate in the blood of the wife in every one of these cases. Whatever this antagonistic relationship was that existed in the blood it was represented in the ovum and the spermatozoa, and it stood to reason that if a spermatozoa penetrated an ovum there would be no blood formation. He felt that this was a line of investigation worth while following out and hoped it would be taken up. If this theory was true, a method of treatment for this type of sterility was open. Injections of small amounts of serum from one to the other of the sterile couple, when the sterility was due to incompatibility of the blood, would after a while produce an immunity, and would render impregnation possible. This theory might account for those cases in which, after being sterile for many years, the woman would become pregnant. It might be that there was some slight exchange of fluids between the couple that after a while produced immunity and made conception possible.

Dr. H. B. CLARK of Albany said that in sterility in cases due to undeveloped uterus or to anteversion the solid glass stem pessary would help in developing the uterus. Its insertion was not difficult and its retention was not difficult. If worn for about three months it did aid conception in a small class of cases.

Dr. J. W. JUDD of Ithaca expressed the opinion that when the male was saturated and steeped with tobacco it rendered the spermatozoa less active. He asked if such a patient gave up tobacco how long would it be before the spermatozoa would recover their normal motility.

Dr. J. DAWSON FURNESS of New York said that several of the men had spoken of examining the semen. It was frequently a very difficult thing to get the semen. If this were merely suggested to the man in 50 per cent. of the cases that would be the last one would hear of them. One could cut that percentage down by having the woman come to the office immediately after intercourse. One could not take the ground that because a man had had a child by his first wife that he was not the cause of sterility if the second wife bore no child for he might have become sterile. As to x-ray sterility, the speaker knew of a case in which a man was sterile for a time, but the sterility disappeared when he was no longer exposed to the x-ray, and it might be that in a woman sterilized by the x-ray ovulation might return after a time. After an abortion one should not perform a dilatation and curettage for sterility. In such cases the sterility was probably due to a closure of the ends of the tubes by exudate, and in such cases one would

have no success with insemination, nor would one have success with this procedure where there was incompatibility. Dr. Furniss said he had had good success with the solid glass stem pessary in suitable cases, and he had had some success with corpus luteum.

Dr. GELSER, in closing, said he thought the point Dr. Furniss had made as to the difficulty of getting the husband to consent to an examination of the semen was a very good one. As to how long it took for the spermatozoa to recover from the effects of tobacco he knew nothing. As to the hemolytic reaction, it would be easier to test the effect of the spermatozoa on the woman's blood; that could be done very rapidly.

Remarks on Fibroid Tumors.—Dr. EDWARD JOSEPH ILL of Newark, N. J., presented this communication, in which he stated that he had made observations on 529 cases of operation for fibromyoma in his private practice and in the hospital with which he was connected. A distinct indication for every operation should precede the work proper. Death resulting from fibroid directly was extremely rare. The vast majority of fibroids occurred in women over 35 years of age, namely, 78.5 per cent. The records of the Massachusetts General Hospital showed that in 127 complete autopsies fibroids of the uterus were present in 33.1 of the cases. In women under 50 years of age, who were examined at autopsy, fibroids were present in 22.9 per cent. of the cases, while in over fifty years of age they were present in 45 per cent. of the cases. At Johns Hopkins Hospital, among 424 autopsies 32.8 per cent. had benign tumors of the uterus. Of those under 50 years of age, 30.1 per cent. had such tumors. Of the colored subjects 49.4 per cent. had benign tumors. According to these statistics, collected by Frederick L. Hoffman, 27.9 per cent. of all women had fibroids. It had been suggested that every woman be examined once a year. This would be a calamity if the woman got into the hands of a "would be" surgeon. His experience was that the presence of a fibroid, the diagnosis being certain, was rarely an indication for operation. However, it was sometimes advisable to perform an operation for fibroid if the patient became depressed because of the knowledge of the presence of the growth. A doubtful diagnosis should always be cleared up by whatever means were at one's disposal. Rapidly growing tumors should be removed. Some cases of fibroid he had watched closely for years because of the fear that they might become malignant, but he had never seen a malignant degeneration of a fibroid. Such degeneration undoubtedly took place, but it was very rare indeed. He had seen sarcoma develop beside a fibroid but never in the tumor itself. A combination of fibroid and cancer was rather frequent but this was not surprising in view of the frequency of both these conditions. The most frequent indication for operative interference was pain, which occurred in 36 per cent. of the cases in the series presented, while hemorrhage was recorded in 35 per cent. of the cases. Here came in the question as to what degree of hemorrhage was considered sufficient to warrant operative interference. A combination of pain and hemorrhage occurred in 13 per cent. of the cases, which went to show that more of the patients had wished relief from pain than from hemorrhage. A most serious and pressing indication for operation was in the presence of symptoms of sepsis. The indication for operation in the presence of septic adnexal disease was debatable. Sterility might be an indication for operation, but operation for sterility was a high ideal and should never be undertaken except for single tumors. Dystocia due to fibroid had been the cause of but one operation. The author had performed operations by the vaginal route for tumors reaching to the navel. To-day vaginal extirpation should not be done if the uterus could not be pushed up into the pelvis, and the cervix brought to the vulva. Abdominal supravaginal amputation would be the operation of choice in most cases. This was the operation performed in 331 of the writer's cases. Abdominal total extirpation was done 14 times; total myomectomy 14 times. In 13 instances he did a myomectomy and Gillian on the same patient. All his myomectomies recovered. He did a curettage 13 times but this was an operation fraught with danger, unsatisfactory, and should rarely be resorted to. He had made it a practice to conserve one or both ovaries. In the first one

hundred cases he had had seven deaths, in the second one hundred he had had no deaths, and in two series of 69 cases each he had had no deaths.

Dr. GEORGE B. BROAD of Syracuse said that before coming to the meeting he had looked over his last 100 cases of fibromyoma of the uterus and analyzed them. In these 100 cases he did 48 hysterectomies. These were all very serious cases with complications, as, for instance, one case of a beginning carcinoma, one of a spindle celled sarcoma, etc. He had had only two deaths in this series, or a mortality of two per cent. The course he was likely to adopt in cases that did not require immediate operation was to give them a preliminary course of x-ray treatment and then if they did not improve after a time he operated. He had six cases in which the x-ray did no good and that had to be operated upon subsequently.

Dr. MARION C. POTTER of Rochester said that fibroids were very common and no one knew when they were going to become malignant. He had been especially interested in the x-ray work. He had had about 12 cases of fibroid that had refused operation, which he had treated with the x-ray or radium with very satisfactory results. Among these cases there were some in women 47 or 48 years of age in which the uterus was as large as that of a five-months' pregnancy, that responded favorably to this form of treatment.

Dr. E. GUSTAVE ZINKE of Cincinnati, Ohio, said that the question of the treatment of fibroids of the uterus was still far from being settled. He was one of the old school who believed that a fibroid tumor of the uterus should receive operative attention and yet he was in no position to criticize the x-ray treatment and there were many cases of cures by the x-ray reported. He, however, had not seen a single case in which the cure was permanent. In many cases the menorrhagia was controlled by the x-ray but he had seen just as many cases which did not respond at all to the x-ray treatment.

Dr. J. L. PFEIFFER of Brooklyn spoke of the necessity of being very guarded in one's diagnosis in cases of fibroid that might be complicated and especially where there might be a complicating pregnancy.

Dr. U. P. SEARS of Syracuse asked Dr. Ill whether the tumors had been examined by a pathologist. Sarcoma of a fibroid occurred most frequently at the central part of the tumor and unless thoroughly looked for might escape notice. It was surprising to see the very low percentage of sarcoma in fibroids. He thought the x-ray treatment very good and especially for the cases with low hemoglobin, in which it was a valuable adjunct in putting them in condition to withstand an operation. He had had no experience with the x-ray and thought twenty years ago that every fibroid must be removed. In some quarters now they said that radium would destroy the fibroid. In 212 cases reported by Dr. Kelly that were treated with radium all got well but eight. It was an interesting thing that the enthusiasm for the x-ray and radium came from exactly the same quarter from which the enthusiasm for operation had formerly come.

Backache from the Orthopedic Standpoint.—Dr. PERCY WILLARD ROBERTS of New York presented this communication, in which he said they had on record as recognized causes of backache faulty attitude, the various chronic diseases to which the vertebrae were liable, strains affecting the lumbar and sacral regions, and the results of fracture and abnormal development of the spinal structures. They had in inherited syphilis unrecognized cause of backache. Several cases of this nature had come to his attention during the last two years.

In 300 cases observed 50 per cent. or more of the joint conditions which had been attributed to tuberculosis were really of luetic origin. It was evident that many adults harbored the *treponema pallida* although none of the classical symptoms of syphilis were produced by their presence. The toxins of these organisms produced such symptoms as headache, myositis, and neurological manifestations, which if the cause were not understood would baffle the most conscientious effort of the physician. The cases of back pain that had been observed in this study fell under the general classification of myositis. Their symptomatology suggested irritation of muscle fiber tissues by some toxic material.

Except for tenderness on deep pressure in the gluteal and lumbar region there were no characteristic features that marked these cases. The diagnostic perplexities they presented might be judged by the fact that they had been treated for a variety of disorders, including uterine displacement, iliosacral strain, Potts disease, scoliosis, and floating kidney. A study of the teeth was of assistance in making the diagnosis of syphilis since the dental site was a favorite point for the colonization of the spirochete in syphilis. In order of importance the abnormalities that were found in the teeth were abnormalities in the form of the first molars, wide spacing of the incisors, smooth tipped molars, and enamel defects of various teeth. Dental evidence of syphilis was not always conclusive but it was of help in making the diagnosis in a considerable number of cases. Dr. Roberts illustrated his paper with lantern slides.

Dr. ALBERT VANDER VEER of Albany recalled the time when all backache was attributed to antelexion or retroversion of the uterus and much harm must have been done by the forcible lifting up of the uterus. Those were dangerous days before the importance of infection was recognized and undoubtedly there were many cases of infections by uterine sounds which were called cellulitis and pelvic peritonitis, and which resulted in abscess in the cul-de-sac. Ever since those days they had been trying to find the cause of backache. After the days of asepsis and antiseptics arrived they began to look for the cause of backache in other organs than the generative organs. Then came the days when operative interference was the popular treatment for backache. They then passed to the study of the effect of posture and many were brought to understand that the wearing of high heels caused a faulty posture which was responsible for the backache. Then came the introduction of the relief of flat foot and it was found that the relief of flat foot relieved backache. It was found that in some cases the backache was due to the condition of the intestines and there were certain cases in which the trouble was with the psoas muscle. They had later come to attribute backache to infection of the tonsils in some cases and in other cases even the removal of the appendix had relieved the backache. Having passed through all these periods, the writer felt that he had gained some experience which would help in the diagnosis of backache and its treatment, and it all led up to the laboratory period. By looking for the cause of the condition in the secretions of the body one came nearer to the diagnosis. It was to the laboratory that they owed their knowledge of the causes of backache.

Dr. LORING T. SWAIM of Boston said that in looking over orthopedic cases he found that cervical spine was often overlooked and the case called one of neurasthenia. The eyes and throat would be examined in these cases and nothing would be found. A cervical spine was usually associated with a low back and 75 per cent. of low back cases were largely due to myositis.

Dr. JAMES E. KING of Buffalo said there were three points to be considered: sacroiliac joint disease, cases of vertebral relaxation associated with enteroptosis, and floating kidney. Each of these he discussed. In searching for the cause of backache he thought the pelvic organs were the last to be considered. After every other cause had been eliminated one might then seek it in the pelvic organs.

Dr. U. P. SEARS of Syracuse said he was very glad to have it brought out that syphilis was one of the chief causes of backache. He had formerly been a gynecologist and was now engaged in public health work and it was important that the gynecologist and the physician should bring about a proper sentiment in reference to venereal diseases. Why could not syphilis be eradicated in the twentieth century as smallpox had been in the nineteenth? Syphilis was doing more injury to our Army today than all the German bullets.

SECTION ON SURGERY.

First Day—Tuesday, May 21.

DR. THOMAS LAURIE OF SYRACUSE IN THE CHAIR.

Congenital Malformations of the Spine, with Report of Cases.—Dr. CHARLES D. REID of Syracuse made this

presentation. This study was confined to general remarks on those cases which were not considered as entirely amenable to correction. It was often found necessary to employ palliative measures in their treatment. The lesions varied from slight irregularity to a complete absence of an organ. As yet no satisfactory classification had been made of the condition. Heredity no doubt played a part as in families where one deformity was noted, careful examination often revealed the fact that other members of the family had some congenital malformation. Among causative factors no doubt maternal trauma, lack of nourishment and placental malformation were included. Intrauterine diseases of the fetus, such as syphilis or rickets, also had a share in producing these conditions. An asymmetrical attachment of the muscles was often coincident with maldevelopment of vertebræ. Of all malformations, spina bifida was the most common, and one theory held that this was due to an oversecretion of spinal fluid, as when operation was done and closure made, a hydrocephalus often resulted. In vertebral opening with loss of closure of the sphincters, operation was rarely successful, and any operation should be made within the first few weeks of life in order to insure any favorable result. Other deformities seen were fusion of ribs, lack of ribs, or an abnormal number of vertebræ. In regard to treatment, much could be done to relieve pain, by support by means of plaster jackets, proper exercise, etc. Bone graft operations were sometimes employed with some improvement. In some cases the sacralization of lumbar vertebræ was found to be the cause of symptoms. Wherever persistent backache existed the vertebræ should be examined. Occasionally a cervical rib was found attached to the 7th cervical vertebra, and where this caused symptoms its proper treatment was by removal. In conclusion it should be said that this condition was by no means a rare one, that careful x-ray studies were necessary to clear up the diagnosis, and that operation would be successful on carefully selected cases.

Dr. HOWARD L. PRINCE of Rochester said that these cases with spinal deformities had not been studied enough. Spina bifida was no doubt a much more common condition than was generally supposed. The more x-ray pictures were made of children, the more cases were found. He would be a little more pessimistic about the results of surgery than was Dr. Reid, who said there was a mortality of 44 per cent. Dr. Prince said he would place this at a higher figure. In spina bifida work where there were no complicating conditions, a very young patient might be benefited. In regard to scoliosis, few cases were explained by the gross anatomic lesions. At the American Orthopedic Association meeting, Dr. Abbott of Maine stated that he had seen cases of lateral curvature cured, but upon examination it was found that the cases were not really cured. Gradual improvement might be achieved with the use of jackets, but in a few years the x-ray would show that the conditions were about the same. A mild case could be kept fairly well by exercise and care of the muscles, but serious cases, in spite of discomfort and sometimes agony of treatment, would leave off pretty much where they started. Was the misery caused worth the effort expended? In cases of sacralization of lumbar vertebræ, no exact data could be obtained. He would wish to make a plea for the more careful examination for the causes of backache. Patients were examined for conditions of the pelvis, for chronic appendix, or for kidney conditions, but few examinations of the vertebræ were made. Physicians were apt to talk about cases more than they were apt to look for end results.

Dr. C. OGILVEY of New York said they had been hearing very pessimistic accounts of overcorrection of the spine, but Dr. Reid's paper was really upon malformations of the spine. There might be a lateral deviation of the spine without bony deformity, or there might be actual malformation of the bony structure. These occurred more frequently than was generally recognized. There was no excuse for this non-recognition, and if cases were treated early enough the opportunities for correction would be much greater. It was not always possible to correct the spine, but one was often able to put it into its relation with the weight bearing function of the body. In one case of a boy with ac-

cessory lumbar vertebrae, a compensatory curve had occurred which adjusted the spine to the weight bearing capacity.

Dr. C. ROWLEY of Hornell said in one case he had seen of complete spina bifida, from the occipito-parietal to the third lumbar vertebrae, the deformity was so extensive as to prevent delivery through the brim of the pelvis.

Dr. G. D. GREGOR of Watertown said that in making examinations on the advisory board he had come across one case of a man who had suffered injury to the cervical spine. There was no neck to be seen, the head being set directly upon the shoulders. The man complained of nothing except limitation of motion of the head. The x-ray showed three sets of cervical ribs up to the occiput.

Dr. C. D. REID said, in closing, that he agreed with Dr. Prince that operative mortality was high and the results poor. One could not cure a lateral curvature, but these cases could be improved to a great extent if they were seen in early life.

The Role of the Anesthetist in the Surgical Team.—Dr. J. J. BUETTNER of Syracuse presented this subject. He emphasized the need of closer cooperation between surgeon and anesthetist, by the interchange of papers and discussions in joint sessions devoted to these subjects. It should be borne in mind that the operation was for the benefit of the patient, and therefore any means conducive to this end should be utilized. The anesthetist was being more and more recognized as a specialist and the past ten years had seen wonderful progress in the art of anesthesia, and studies were being made as to means of avoiding unpleasant after effects, such as nausea, vomiting, etc. To these efforts the laboratory technician and the urologist had contributed much data which had a bearing upon safe and successful results. Students should possess both theoretical and practical knowledge of anesthesia and should be under the guidance and instruction of an expert anesthetist. Now, in the present crisis, as never before, anesthesia was called upon to perform wonderful service, and it became more and more necessary to consider the choice of the anesthetist from the point of view of the patient, rather than of the surgeon. Ether, in inexperienced hands, was the safest anesthetic, but in skillful hands nitrous oxid and oxygen gave far more favorable results, both in regard to happier induction and easier convalescence. These facts should be sufficient to induce competent surgeons to turn their attention to this mode of anesthesia. Patients frequently had so great a dread of anesthesia that they had been known to procrastinate operation to their own doom rather than undergo the extreme discomfort which it occasioned.

Dr. D. H. MURRAY of Syracuse said he was in hearty accord with all the statements presented. He had presented a paper 18 years ago upon this same subject, in which he had made the statement that "..... all persons dying under anesthesia are killed by the anesthetist." He had been taken to task by a prominent surgeon for making this statement. He believed, however, that if this surgeon lived long enough he would find out the truth of the remark. He considered that the best possible anesthetist should be chosen to assist the surgeon, as this was the most important factor as far as the life of the patient was concerned. He had known a recent case where, the interne being allowed to give the anesthetic and paying more attention to the operation than to the patient, the latter had died, in spite of all efforts to save him. This was likely to occur at any time, where the junior interne was chosen to give the anesthetic. Colleges and hospitals were to blame for this situation; the former because they did not teach the principles of anesthesia, the latter, because they did not understand its great importance. It was far better in the interests of good surgical team work that the junior interne should act as assistant, and the senior interne be allowed to administer the anesthetic.

Dr. R. H. TRICK of Buffalo said that he had had the same experience that Dr. Murray had had. He had also presented a paper on this subject, but he had dwelt on the psychological aspect of anesthesia in the pre-operative preparation of the patient. Few internes

took real interest in this subject. One had to train them and interest should be developed or the patient was subjected to unnecessary danger. Changes were made so frequently in the staff, that by the time a man had learned to give an anesthetic he was transferred to another part of the service.

Dr. PARKER SYMS of New York said that this subject was of the highest importance to the success of surgical treatment. He felt that they had retrogressed, rather than progressed, in staff organization. It was impossible to get good surgical team work where the internes were changed every few months. In his hospital service he had 4 new house men and a new assistant every year, so that no traditions were handed down, but it was necessary to begin instruction all over again every year. This was the result of trying to compromise with the truth and to give the men what they wanted and not what was the best practice. With 18 months thorough training in medicine or surgery a young man had a chance really to learn something. The anesthetist was of the highest importance to the competent surgeon and the position should be made attractive enough in the hospitals to secure the best type of men. In order to avoid the dangers of putting the work of anesthetizing into the hands of the interne, frequently good results were obtained by allowing a specially trained nurse to have entire control of the work.

Dr. J. D. LUCEY of Stapleton, S. I., said that a paper of this kind was extremely well-timed. It was most necessary at the present time that good anesthetists should be available for service. Of the two men, it could be said that greater skill was required by the anesthetist than by the surgeon. He felt that a good surgeon fully appreciated the aid of a skilled anesthetist. In his experience he had seen deaths occur from chloroform but not from ether. He would like to emphasize one point, that was that one could not get a good anesthetist for a five dollar fee. This was the rate in country districts, and the services rendered were worth about that sum.

Dr. J. J. BUETTNER in closing said that the importance of anesthesia had not been fully recognized. The subject was largely neglected by medical schools and hospitals and to achieve success there must be a change on all sides. There seemed to be a place for the specially trained nurse as an anesthetist. The tendency of the interne to watch the operation rather than the patient opened a source of danger. The present war situation emphasized the importance of an alteration in the attitude of the profession towards this subject and the scientific aspect of anesthesia was slowly but surely coming into its own.

Dynamics of Abdominal Hernia.—Dr. HARRY R. TRICK of Buffalo read this paper. He said that the great number of procedures advocated indicated the fact that there was a lack of definite knowledge of any particularly desirable method. The fault often lay as much in the understanding of anatomy as in technique. In order to understand the proper arrangement of tissues to best produce repair, the forces that caused hernia must be thoroughly comprehended. If the causes were thoroughly understood, a technique somewhat different from that usually followed would be undertaken. In regard to contributing causes there were included developmental defects, weakness of the abdominal walls and congenital lesions. The direct exciting causes were coughing, sneezing, or violent muscular effort such as would suddenly force an increase in abdominal pressure. A protrusion of an organ through its surrounding envelope was thus effected, the force from behind being stronger than the wall. Intraabdominal pressure could be stated to be the equilibrium between the abdominal wall and the organs it inclosed. When a loop of bowel was forced violently against a weak spot in the wall, an opening was formed, into which the loop became fixed. The treatment of hernia therefore became a question of applied mechanics. In some cases a truss put over the weak spot in the wall would help, especially in children, but in many cases a truss should be condemned and an ill-fitting one was worse than none at all. In these cases herniorrhaphy was the only logical treatment. There was no broad rule to be blindly followed in every case; each case had to be judged separately on its own merits. The individual indications should be studied, and in cases

where a handicap was apparent the surgeon should rely on his own resources and judgment.

Dr. E. M. STANTON of Schenectady said that the conception of this subject should be from the point of view of the force which acted when strain took place. In this way they could get a proper view of the role played by the tissues in repair of the hernia. Surgeons were apt to consider that the muscular fibers of the external oblique would furnish a strong support. This was outside of the real supporting tissue. Great care should be exercised in sewing down the muscle elsewhere to make a firm basis for support.

Dr. C. C. LYTLE of Utica said that the dynamics of hernia were an academic consideration. The presence of hernia depended upon defects in the abdominal wall and the forces exerted against that defect. Intra-visceral pressure was a better term than intraabdominal pressure. The hernia occurred when the force overcame the resistance of the weak spot.

Dr. J. RICHTER of Buffalo said he did not call this intravisceral pressure. It was analogous to the pressure exerted on the amniotic sac by dilatation of the cervix. The pressure on the vessel containing fluid was uniform in all directions.

Dr. G. B. BROAD of Syracuse said that with high power rifle shots striking the skull the pressure exerted was such as to cause the skull to explode, but in this case, with the vessel containing fluid, the pressure came from the vessel itself. It had been said that hernia followed the course of the blood vessels, but femoral hernia, which was more patent than inguinal hernia, was not so common. He would like to know why it was recommended so often to sew down the external oblique. More attention should be paid to the internal conjoint tendon as in cases where there was recurrence in the groin it was found that there was a defect of the conjoint tendon.

Dr. PARKER SYMS of New York said that records showed that Germans had been in the habit of systematically producing hernia in order to escape military service. They inserted the finger into the inguinal canal and this hernia was caused by external abdominal pressure.

Dr. H. TRICK in conclusion, said that with femoral hernia, a lymph node of a piece of fat might act as an additional barrier and so prevent its more frequent occurrence. He thought it was important to consider the transversalis fascia as the starting point. He had heard of the extraabdominal force mentioned by Dr. Syms, but he understood it was practised among the Russians and that hernias occurred through the opening thus made.

Conservative Surgery of Chronic Intestinal Stasis.—Dr. F. C. YEOMANS of New York read this paper. He considered the subject from the viewpoint of abnormal delay in passage of the bowel content, with the resultant accumulation of toxic material and absorption of poisonous products. Delay without toxemia was not considered. Toxemia was prevented by the integrity of the endocrinal system and of kidney function. When stasis was fully established the diagnosis often presented difficulty. Certain cases were supposed to be suffering from chronic constipation. Differentiation of inciting causes should be made and all tests, such as the x-ray, the Wassermann test, examinations of stools after test meals, and examination of kidney function should be made. The colonic function before and after defecation should be ascertained. The Wassermann test must be done to rule out tabs from the diagnosis. Two classes of stasis existed: (1) with obstruction; (2) without obstruction. In the latter, autogenous vaccines, endocrinal therapy, etc., had their place in treatment. The question as to whether there were ever surgical indications could be answered in the affirmative. The treatment of Hirschsprung's disease required surgical interference. In spastic intestinal stasis, caused by putrefaction of the bowel contents and in a general visceroptosis, surgery would be of help. In cases of bands, folds and membranes, operation was not often successful. Radical surgery, such as short-circuiting operations; colectomy, partial or total; cecostigmoidostomy, was successful in about two-thirds of the cases. Partial colectomy was disappointing; often the stasis was removed, but the toxemia persisted. There was no general rule to be laid down as to pro-

cedure. Carefully determined surgery in carefully selected cases would give the results most to be desired.

Dr. M. PACKARD of New York said that he had seen the case of a woman who had all the symptoms of intestinal stasis for twelve years. She became pregnant at the end of this time and during her pregnancy she felt better than she had ever done. After the termination of pregnancy she relapsed into her condition of intestinal stasis. Another case was that of a boy who had a movement of the bowels about once a week. Peristalsis, as watched by the fluoroscope was about once in five minutes, instead of three times in one minute. What was the meaning of these cases? Why had the woman a relief of symptoms during her pregnancy? During pregnancy there was a distinct condition of hyperthyroidism. The problem in the case of this patient was a lack of thyroid secretion, which was only compensated for during pregnancy. Dr. Yeomans had differentiated between mechanical and physiological obstruction. The cases of physiological obstruction were medical cases. They were due to disturbances in the endocrinal system. Mechanical obstruction demanded surgical treatment.

Dr. D. H. MURRAY of Syracuse said that many of these cases lacked a thorough examination. Many of the medical profession did not know much about rectal disease. They had a great distaste for making a thorough rectal examination. He would recall the case of a woman he had seen in a sanatorium who was so prostrated that she could not raise her head without fainting and talking incoherently. She had been under the care of eight physicians, many of them prominent men. No proper rectal examination had been made. The x-ray showed an enormously distended colon, the gas resulting from impaction at the distal end. Ulceration and internal hemorrhoids were shown to be the cause. The woman was removed to a hospital and the hemorrhoids were removed by operation. She made an uninterrupted recovery.

Dr. PARKER SYMS of New York said this had been an unusually good paper. This subject had attracted a great deal of notoriety because of the work of Lane and the profession had been inclined to go to extremes. Dr. Yeomans had given a very good impression of the very limited field of operative surgery in these cases. Efforts had to be limited to the condition causing the obstruction. Short circuiting operations, which resulted in leaving of blind pouches, were not a success. Total colectomy was a serious operation not stood well by the majority of patients. Osler had pointed out the difference between a family doctor and a consultant. The consultant examined the rectum. It was astonishing what relief of symptoms (usually not attributed to rectal disease) would follow the removal of hemorrhoids. Any rectal disease would produce irritability by the unconscious physiological drag. When the surgeon found a movable colon he tried to fix it; when he found it fixed he tried to mobilize it. It would be better to depend on symptoms and not on mechanical conditions before resorting to surgery. By doing slight operations in selected cases the most gratifying results could be obtained. In regard to Jackson's veil the profession would have done better if they had never heard that term. It was only where transverse bands were produced and constituted an obstruction that interference, remote from the bowel, was necessary.

Dr. YEOMANS, in closing, said that sufficient time had elapsed since Lane's work to estimate its value. The most important thing was to reach a basic factor in a given case. Examination into causes would decide whether a given case should be treated medically or surgically. A careful neurological examination should always precede operative measures.

SECTION ON PEDIATRICS.

Second Day—Wednesday, May 22.

DR. T. WOOD CLARKE IN THE CHAIR.

The Early History of Infantile Paralysis.—Dr. LOUIS C. AGER of Brooklyn read this paper, in which he gave a brief summary of the result of a careful search of early medical literature on infantile paralysis. He concluded as follows: (1) Some form of paralysis of

unknown origin was sufficiently common in Asia to have attracted the attention of Boerhaave before 1701. (2) Infantile paralysis appeared in England some time between 1784 and 1799; judging from the writings of Underwood. (3) It did not appear on the continent until fifteen or twenty years later. (4) The disease prevailed to some extent among Anglo-Indian children about 1800 if not earlier and its victims returned to England at least as early as that date. Although the evidence was by no means conclusive, it seemed reasonable to accept the theory that acute infantile paralysis existed in India and Asia originally, and was brought to England by Anglo-Indians, and then transmitted to the continent. This review was brought up to the work of Heine. As the period after Heine had been reviewed in a masterly manner by Dr. Mary Putnam Jacobi in 1873 it was not necessary to discuss it in this paper.

The Longitudinal Sinus; Its Adaptability in Procuring Blood for Diagnosis; Its Use in Transfusion of Blood and for Diagnostic Purposes; an Ideal Method in Infancy.—Dr. LOUIS FISCHER of New York presented this paper. The simplicity and ease of reaching the sinus located at the posterior aspect of the anterior fontanel, compared with the difficulty of entering the median basilic or the femoral vein in infancy, made the sinus route a matter of preference. The ease with which blood could be obtained by this channel for such purposes as the Wassermann test or for transfusion was very advantageous for the infant. Time was of value in dealing with the young marasmic infant and often much time was lost in endeavoring to enter a vein. In convulsions blood could be immediately extracted, with relief to the little patient, by the sinus route. This method at once served to relieve intracranial pressure. The method would answer well the purpose of obtaining sufficient blood for cultures, and was also indicated in injecting diphtheria antitoxin in cases in which it was desired to bring the antitoxin into the circulation quickly. In transfusion for hemophilia the method gave excellent results. The infant should be wrapped in mummy bandage and placed flat on its back on the table, with the head steadied. One or two millimeters was sufficient depth for insertion of the needle as the sinus was very superficial. The blood could be removed by aspiration. Careful note should be taken of the color, pulse, and respiration of the infant. In using this technique, care should be taken that the needle and the skin be sterile and if this were done, no infection need be feared. Cases were cited in which marked benefit was derived by this procedure in transfusion for hemorrhage in blood letting for convulsions and in cases where marasmic infants were transfused.

X-Ray Plate Demonstration of Types of Vomiting.—Dr. DEWITT HALSEY SHERMAN showed these plates for the purpose of demonstrating the way in which x-ray plates would aid in the diagnosis or in clarifying diagnosis. The first set was that of a baby five weeks old, always breast fed, that soon after birth vomited considerably. At first it gained weight, but as the vomiting increased it lost. At times it vomited much more in bulk and much more frequently than at others. It rarely vomited large amounts. Its stools were normal at times both in character and in size, and then would be small in direct accord with the intake of food. It had no pain and suffered only from hunger and thirst. Careful physical examination revealed no pyloric tumor. Though pyloric stenosis was the undoubted diagnosis, there was still enough evidence to consider pylorospasm and treat it for a few days. The baby was given chloral and bromides. These at first seemed to act favorably but soon there was a relapse. The diagnosis was definitely corroborated by the x-ray plates. When the infant was under anesthesia a small tumor could for the first time be felt. The Ramstedt operation was performed by Dr. Thew Wright of Buffalo and the result was as dramatic as was usual in those cases if the delay had not been too long. In the second case the vomiting did not begin until the infant was five weeks old. The speaker thought he felt a tumor and with the x-ray the diagnosis was confirmed. The Ramstedt operation was performed when the child was six weeks of age with results equally as brilliant as in the first case. In the third case, intestinal ob-

struction, either intussusception or volvulus, was suspected because of persistent vomiting, the recurring pain, the history of not having passed any gas, and because of the absence of stools except by irrigation. The results of the irrigation did not show blood or mucus. No tumor could be felt. The child was radiographed and obstruction excluded. It was soon put on a fat free diet, given chloral and bromides, and made a rapid recovery. The final diagnosis was pylorospasm, high fat with acetoneuria acting as contributing and subsequent factors. The fourth case came to the speaker with the history of food intolerance and with the special symptom that it vomited almost anything it took, no matter what modification of milk or proprietary food was used. The baby did well, after starvation on diluted eiweiss milk, but in a few days started another period of vomiting. The eiweiss milk was not tolerated. A marked change followed the use of flour ball, and from the time it received its carbohydrate in this form it progressed well. In these neuropathic cases, after having eliminated the special food element or elements whose tolerance had been particularly broken, the speaker found that chloral and the bromides worked quickest, and atrophine next in the relief of vomiting. It was best to treat these cases as hemophilias, giving them a calcium lactate, phosphorus, and cod liver oil. Dr. Sherman also exhibited a plate that showed an intussusception clearly. The last case discussed was one of subacute or chronic intussusception, with mild recurring attacks of vomiting and pain. The radiogram showed the decreased lumen of the bowel. Operation was refused and a few days after the child left the hospital she passed what the mother described as a piece of bowel. Dr. Sherman was inclined to believe from the mother's description that she was correct in calling what came away a piece of the bowel.

The Care of Children Before and After Tonsillectomy.—Dr. CHARLES HENDEE SMITH presented this paper, in which he considered certain medical aspects of operations upon the adenoids and tonsils, the importance of which was frequently overlooked. Before advising that a child should have an operation for enlarged tonsils it was important that his general condition be taken into consideration as well as his throat. A careful history and examination of the child, of his urine and blood, were necessary in order to rule out organic disease. Children who had active tuberculosis should never be operated upon. Hemophilia had also embarrassing possibilities. Other diseases, especially leucemia, Hodgkin's, and syphilis, might cause enlarged tonsils. A blood examination beforehand would sometimes avert a distressing situation after an operation. It was desirable to try to improve the nutrition of markedly undernourished children by rest and feeding for a few weeks before operation. After operation the child was entitled to an anodyne and should be kept in bed for five to seven days, with careful nursing and feeding. Preparations should be made to treat hemorrhage if it occurred. In the Nutrition and Cardiac Classes of the Bellevue Children's Medical Division there was a considerable number of children who were undernourished or who had heart disease referred for tonsillectomy every year. It was found very early that the loss of weight following operation was excessive when the children were discharged in twenty-four hours. They then adopted the plan of transferring these children from the Throat Wards to the Children's Wards on the day after operation. Since this had been done the results had been much more satisfactory, the loss of weight much less and the recovery more prompt.

Third Day—Thursday, May 23.

Meeting at State Training School for Girls.—The Pediatric Section spent Thursday in making a trip to the State Training School for Girls at Hudson, N. Y. After a tour of inspection of the institution a meeting was held, at which Dr. Lewellys F. Barker of Baltimore discussed the "Faulty Training of the Nervous Child" and the problem of "Adolescent Delinquency" was discussed by Dr. Anna Tefft Bingham of New York City, Dr. William Healy of Boston, Mass., and others.

A BRIEF BIOGRAPHICAL SKETCH OF FOUR PHYSICIANS OF THE NAPOLEONIC ERA.*

BY PAUL E. BECHET, M.D.,

NEW YORK.

IT might be of interest at this moment, now that we have joined the fight against autocracy, to recall to the memory of the profession four members of their fraternity who a little more than a hundred years ago were engaged in a similar contest. It is interesting in passing to note the similarity of the objectives of the war of 1792-1815 and the present one. In both the rights of the people were at stake; in both it was a struggle between democracy and autocracy. We talk of the debt we owe France for her help at the birth of our republic, but we forget the greater debt we owe her for the manner in which she carried the banner of democracy against all of Europe for 23 years. It is to her and her great Captain that the present free peoples of Europe must be grateful. No nation offered a more inspiring spectacle than did France in her fight to keep inviolate her rights and liberty. It was strange that she was at last overcome and Bourbonism saddled upon her through the efforts of the nation who is now the greatest champion of those rights she denied to France, and whose treatment of Napoleon, despite her apologists, will always remain a blot upon her standard. We are now in the midst of the great struggle foretold by Napoleon when he stated that "in fifty years the world would either be free or Cossack." He used the word Cossack because at that time it expressed everything that the word Prussian represents today. Another peculiarity of the two world wars is that in the past one all of the world was leagued against democracy, and in the present one the opposite is true; if an augury can be drawn from this, Germany will be defeated; fortunately if such prove the case right will prevail over might—not might over right as occurred one hundred years ago. Among the great men grouped around the genius of Napoleon, our profession was well represented. While the rank and file did their full duty Larrey, Corvisart, Desgenettes, and Antommarchi are best remembered, the last named particularly, because of the melancholy duty of assisting at the termination of the St. Helena tragedy. Of the four Larrey is the best known, mostly because of his contributions to military surgery. He was the first to make a practical use of field ambulances, and did much to hasten the removal and ameliorate the suf-

ferings of the wounded to whom he was always as a father.

Jean Dominique Larrey was born in 1776. At the age of 19 he received a commission as assistant surgeon in the French Navy. At 21 he was chief surgeon on a frigate engaged in the protection of French fishermen on the Canadian Coast. On his return to France he entered the Royal Hospital, and treated the wounded after the storming of the Bastille. At the outbreak of the Revolution he adopted the new republican principles, and joined the Republican Army. In 1793 at the siege of Mainz, he brought into use for the first time the

FIG. 1.—Jean Dominique Larrey.

military ambulances, which were called at that time "ambulances volantes." These gave such satisfaction that they were thereafter in general use in the armies of the republic. About the same time Baron Pierre François Percy (1754-1825) organized a corps of brancardiers or stretcher bearers. So it is to these two men that credit must be given for the first efforts at quick removal of the wounded during the progress of a battle. Larrey accompanied Napoleon to Egypt, and thereafter in every one of the campaigns. It was during the retreat from Moscow that he rendered most valued services, being particularly successful in the treatment of frost-bite. In 1807 he was created a

*Read before the Section on Historical Medicine of the New York Academy of Medicine, January 16, 1918.

Knight of the Iron Crown and in 1809 a Baron of the Empire. He died at Lyons in 1842. Napoleon's opinion of him, which I quote in full from O'Meara's "Napoleon in Exile," is a good summing up of the character of this man of sterling qualities: "Larrey was the most honest man and the best friend to the soldier I ever knew. Vigilant and indefatigable in his exertions for the wounded, Larrey was seen on the field of battle, after an action, accompanied by a train of young surgeons, endeavoring to discover if any signs of life remained in the bodies. In the most inclement weather and at all times of the night or day, Larrey was to be found among the wounded. He scarcely allowed a moment's repose to his assistants, and kept them eternally at their posts. He tormented the generals, and disturbed them out of their beds at night whenever he wanted accommodations or assistance for the wounded or sick. They were all afraid of him, as they knew he would instantly come and make a complaint to me. He paid court to none of them and was the implacable enemy of the fournisseurs." A clause in Napoleon's will reads as follows: "To Larrey, surgeon in chief, 100,000 francs. He is the most virtuous man I have ever known." The two most important of Larrey's contributions to medicine were the "Relation Historique et Chirurgicale de L'Expedition de l'Armée de l'Orient en Egypt et en Syrie" and his "Mémoires de Médecine et de Chirurgie Militaires," four volumes, 8vo. Paris, 1813-18.

Corvisart

Fig. 2.—Jean Nicolas Corvisart.

Jean Nicolas Corvisart was born in Drécourt, France, on February 15, 1755. His father wished to make a lawyer of him, but young Corvisart showed no special aptitude. By accident he happened to hear some lectures given by the celebrated physician Antoine Petit, which soon convinced him that medicine was his true vocation. Despite the poverty of the family and the opposition of his father, he studied under Desault and Desbois de

Rochefort. In time he was appointed attending physician to the Hôpital de la Charité. During the Consulate he was employed by the Government, and during the Empire became First Physician. His public and private practice took up so much time that in 1807 he felt obliged to resign several chairs in medicine which he had occupied up to that time. After the fall of the Empire in 1814, he retired to his country place and did not again occupy a place in public affairs. He died on September 18, 1821. His principal medical work was the "Nouvelle Methode pour Reconnaître les Maladies Internes de la Poitrine par la Percussion de cette Cavité," Paris, 1808. This book, though a translation of Auenbrugger's work, was greatly added to by Corvisart. Corvisart occupied the position in relation to Napoleon that Larrey occupied to the army; he was Napoleon's First Physician from the early days of the Consulate to 1814, and in almost daily intimate contact with him. The emperor had great confidence in his ability as a physician, and frequently consulted him in relation not only to himself, but also to his family. In 1812 he wrote to Mme. Montesquieu: "I have confidence in the medical skill of my First Physician Corvisart." Corvisart's salary amounted to 30,000 francs a year, to which must be added an allowance of 30,000 francs attached to his title of baron. He was, however, frequently in debt, as he was rather fond of a gay life. With his old friend Guéhéneuc, the vaudevillists Barré and Desfontaines, the ballet master Despréaux, and other bon-vivants, to say nothing of the female sex, many little fêtes of a not too gentle kind took place. He was also very fond of the chase, and loved to hunt at his country place of La Garenne. When on these hunting trips he never stated where he was going for fear of being disturbed. He had a passion for curiosities, pictures, and objects of art, and received many rare curios from Josephine, Marie Louise, and other patients. He attended Napoleon on Wednesdays and Saturdays, usually during the morning toilet, being frequently received with such jokes as "You there great quack, have you killed many people to-day?" to which Corvisart would reply in kind; thereupon his ear would be pulled and rubbed, a great trick of Napoleon's when in good humor and with the people he liked. When the emperor's health was not discussed Corvisart delighted in showing Napoleon some of his curios. He was particularly fond of a stick which formerly belonged to Jean Jacques Rousseau, for which he had paid 1,500 francs.

René Nicolas Dufriche, Baron Desgenettes, was born in Alençon in 1762. He first studied in Paris and later at Montpellier, where he took his degree in 1789. He served throughout the campaign in Italy, and as a reward for his services became surgeon in chief of the army in Egypt, where he again distinguished himself. It was at Jaffa that he inoculated himself with the plague in order to revive the courage of the soldiers. On his return to Paris he was made physician in chief of the Military Hospital, and in 1804 inspector general in the medical service of the army. He was active in the campaigns of Prussia, Poland, Spain, and Russia. In 1800 he was appointed professor of physics and hygiene at the Ecole de Santé. During the retreat from Moscow he was taken prisoner, but was soon

exchanged and returned to the Grand Army. After the battle of Leipsic he was detained by the Allies, and did not reach France until May, 1814. During the hundred days, Napoleon evidenced great confidence in him; he was given the appointment of

voted much of his time to surgery. He then moved to Florence, where he served an apprenticeship under Mascagni. He was professor of anatomy at Florence in 1819 when he was selected by Cardinal Fesch, Napoleon's half uncle, and Madame Mère, Napoleon's mother, to succeed O'Meara as the emperor's physician, O'Meara having been banished from St. Helena by Sir Hudson Lowe for his devotion to Napoleon's cause; the emperor had been without medical attendance for about two years. Antommarchi accepted the commission and, in company with two priests and two domestics, traveled slowly through Germany, arriving in London on April 19, 1819. Here he met with all kind of difficulties and numberless delays. Offers and insinuations were thrown out in order to prevent his departure for St. Helena. It was then that he had frequent conversations with the faithful O'Meara, and Mr. Stokoe, the surgeon of the Conqueror, who had attended the emperor on a few occasions the preceding winter. He had been forbidden to repeat his visits to the emperor, and sent to England at once by Sir Hudson Lowe, because of his sympathetic attitude toward Napoleon. Antommarchi was at last permitted to take passage on a small trading vessel, which was insufficiently provisioned. After a long and disagreeable passage, subject to many inconveniences, he and his companions arrived at St. Helena on the 18th of September, 1819. He soon gained the confidence and intimacy of the emperor, becoming a companion as well as a physician. Napoleon's fatal illness progressed so rapidly that early in March, 1821, he became confined to his room. On the 28th of April, feeling the end near, the emperor gave Antommarchi instructions about opening his body; he asked him to carry a detailed report of the post-mortem findings to his son, and to instruct him as to the best means of avoiding the disease which had killed the father. He wished to be buried with his ancestors in the Cathedral of Ajaccio in Corsica. On the 2d of May Napoleon became delirious. On the 4th he could take nothing but a little orange flower water, swallowing with great difficulty. Within a few minutes of 6 o'clock on the 5th of May, England's prisoner was no more. Throughout this trying ordeal Antommarchi was in constant attendance. He performed the autopsy, finding a cancerous mass, involving a large part of the stomach, with complete perforation of its walls about an inch from the pylorus. He accompanied the body to the grave, and on the 27th of May embarked for Europe with the rest of the emperor's devoted household. It would be of passing interest here to mention that one of them remained behind mounting guard over the grave of Napoleon for 20 years. As a reward for this extraordinary devotion, he lived to see in 1841 the return of the ashes of France's son to the soil he had loved so well. Antommarchi on his return to Europe partook in the general opprobrium of all those who had served Napoleon faithfully. He lived in poverty in England, Italy, and eventually in France. In the latter country he published a monograph on the famous death mask of Napoleon, which he was supposed to have made immediately after death. It was at this time that he was accused of scientific inaccuracies in various of his medical works, particularly in the publication of Mascagni's anatomical plates, which he was accused

René Nicholas Dufriche

FIG. 3.—René Nicholas Dufriche, Baron Desgenettes.

physician in chief to the Imperial Guard, and was present at Waterloo with this immortal legion. For these services to Napoleon the Bourbons demoted him to the rank he had occupied at the beginning of his career, and it was not until 1819 that his rank was restored. In 1830 he was physician in chief at the Invalides, and mayor of the 10e arrondissement de Paris. He wrote a number of medical works, the most interesting of which was his "Histoire Médicale de l'Armée d'Orient," which was published in 1812.

F. Antommarchi, Italy.

FIG. 4.—Facsimile of Francesco Antommarchi.

The last medical man to share Napoleon's confidence, who remained with him to the very end, trying to alleviate his intense sufferings with whatever slender means he had at his command, was Francesco Antommarchi. He was a compatriot of Napoleon's, having been born in Corsica in 1780. He received his degree at Pisa, after having de-

of having plagiarized. In 1831 he went to Poland in order to give medical aid to the defenders of that unhappy country. He eventually emigrated to Cuba, where he died in 1838. His best remembered book is the "Memoirs of the Last Moments of Napoleon," 2 volumes, Paris, 1825.

40 EAST FORTY-FIRST STREET

LOW DIASTOLIC AND HIGH PULSE PRESSURE IN THREE CASES OF ANEURYSM OF THE AORTA.

BY CHARLES E. STEWART, M.D.

BATTLE CREEK, MICH.

A LOW systolic blood pressure with a high pulse pressure occurring in three cases of aneurysm of the aorta which have recently been under my care prompts me to report them.

CASE I.—The first case is that of a traveling salesman thirty-nine years of age, whose family history is unimportant. As a child he enjoyed good health; during the Spanish-American war he contracted malaria, and this, together with migrating pains in various parts of his body, kept him ill for a year. He had a Neisserian infection in 1899, but denied ever having had lues. At the time of his application for examination he stated that with the exception of an occasional bilious attack, which was accompanied by more or less vertigo, he was feeling well.

Physical examination revealed a small frame, nutrition slightly below normal, net weight 125 pounds, muscles of medium size and flabby, skin normal in color and texture, and a small amount of subcutaneous fat. Several small scars on left side of neck occasioned by suppurating glands when a child. Chest was small, expansion somewhat limited, resonance normal. The

FIG. 1.—Case I. Roentgenogram showing anterior view.

heart dulness was increased transversely, the apex beat was in the fifth interspace one cm. inside the mid-clavicular line. On auscultation a diastolic mummur was heard at the aortic area and was transmitted in all directions, especially toward the apex and over the right pectoral region.

At this time a fluoroscopic examination of the chest revealed "a diffuse dilatation of the heart amounting to about 25 per cent." Urine and blood examinations were negative. Systolic blood pressure 104, diastolic pressure 26, pulse pressure 78. At the time the low diastolic pressure was thought to be due to what was sup-

FIG. 2.—Case I. Roentgenogram showing an oblique view.

posed to be an aortic insufficiency, which diagnosis later proved to be incorrect.

The patient remained under observation for a few days only, stating when he left that he was feeling splendid. On account of the supposed organic heart

FIG. 3.—Case I. Showing aneurysmal sac,

lesion he was advised against overexertion and to keep in touch with his home physician, which he promised to do.

On November 30, 1915, nearly two years later, he again applied for examination and treatment, stating that since his former visit he had been enjoying good

health until in February, 1915, when after contracting a cold, he experienced a severe pain in his right chest, a little to the right of the sternum and an inch and a half above the level of the nipple; in this region he could feel a "rasping sensation." He described the pain at first as being of a dull aching character, which soon developed into a sharp one, which passed through his chest and side and also into his shoulder and arm, being most intense on the right side. The pain was increased by exercise and relieved by rest in a recumbent position. Heat over the painful areas also gave relief.

For three or four weeks prior to examination the pain had been growing more severe and he had resorted to the use of codeine and iodides with only temporary relief. These pains were so severe that he could not get to sleep for several hours after retiring. He also complained of an aching in his chest as though the muscles were overstrained.

The physical examination at this time revealed a small frame, nutrition considerably below normal, small scars on left side of neck, small amount of subcutaneous fat, skin anemic, dark rings about the eyes, glands negative, tongue coated. Face had an anxious, painful expression. Chest of medium size, large and forcible area of cardiac impulse at apex in fifth interspace in midclavicular line. Veins of neck engorged and pulsated vigorously, jugular bulb large. Chest expansion somewhat limited, respiratory sounds harsher than normal. On palpation a definite well-defined thrill was felt over a large area to the right of the sternum, extending as far out as 1.5 cm. beyond the midclavicular line and of maximum intensity, at the midclavicular line in the third interspace. The thrill was felt as low as the sixth rib and was diastolic in time.

The cardiac dullness was increased in its transverse diameter, extending to the right in the second interspace about 8 cm. from the midsternal line and about 10 cm. to the left in the third interspace.

On auscultation a loud diastolic murmur was heard over the entire pulmonary area above the sixth rib on the right side, both anteriorly and posteriorly, being transmitted into carotids and subclavians, it was also heard over left chest adjacent to the sternum and was of maximum intensity at the midclavicular line in the third interspace, being the area where the thrill was most pronounced. The murmur was very loud and prolonged and during deep inspiration was preceded by a systolic murmur which was confined to an area about the size of a silver dollar. The urine examination was negative; blood examination showed a mild degree of anemia. Systolic blood pressures varied from 140 to 160, diastolic 30 to 40, pulse pressure 100 to 120. A Wassermann test was strongly positive. The x-ray examination was as follows: "There is a rounded bulging the size of a goose egg, apparently at the beginning of the aorta. It has a distinct expansile impulse of its own which is systolic in time. The heart is normal in size."

Two weeks later the patient was found dead in bed, apparently having died while asleep. At autopsy the right pleural cavity was found to be entirely filled with liquid and clotted blood, the heart was slightly enlarged, an aneurysmal sac was discovered about 1.5 cm. above the aortic ring; it was about 5 cm. in diameter and communicated with the aorta by a comparatively small opening; the walls in most places were exceedingly thin and a small buttonhole aperture was observed on the right side of the sac adjacent to the lung. There was diffuse dilatation of the aorta for a distance of 6 cm. beyond the aneurysm. The aortic valves were competent and gave no evidence of sclerosis or other pathological change.

The finding of these valves intact naturally led me to seek for some other cause for the persistently low diastolic pressure. A study of the records of two other cases of aneurysm of the arch of the aorta which had been under my care within a year revealed a close similarity as far as the diastolic pressures were concerned.

CASE II.—Hebrew, male, age 47, merchant, applied for examination in order to determine the cause of a "constant throbbing all over his body." His family his-

tory showed that one sister died at 25 of pulmonary tuberculosis and another at 55 of pernicious anemia. He was robust as a boy and young man; at 19 contracted lues. During the past six months he has been troubled with a constant throbbing all over his body, which at first kept him from sleeping. At present he is not disturbed very much by it. His systolic blood pressure has been as high as 180. He experiences no headaches or vertigo. Bowels are chronically constipated; has used very little tobacco or alcoholics, and has been a hearty eater.

Physical examination: Well developed, skin and mucous membranes anemic, muscles flabby, cutaneous and deep reflexes normal. Pupils unequal, right smaller than left, both react to light and accommodation. Chest of normal size, expansion normal. There is a wide area of dullness over the upper sternal region extending both to right and left. There is forcible pulsation in episternal notch, which can be readily seen, and on palpation a receding and advancing resistant mass is felt which pushes the palpating fingers upward with every systole of the heart.

On auscultation a low systolic murmur is heard at the apex; this increases in intensity as the base is ap-

FIG. 4.—Case II. Roentgenogram showing anterior view.

proached where both systolic and diastolic murmurs are heard. These murmurs are transmitted into the neck and along the subclavians. Palpation over the episternal space and right supraclavicular fossa elicited a well-defined thrill which was coincident with ventricular systole.

The radial arteries were palpable and hypertonic. The systolic pressure ranged from 158 to 168 and the diastolic 48 to 50, pulse pressure 110 to 118. Wassermann test gave positive reaction. The x-ray examination revealed an aneurysm of the arch of the aorta at the junction of the transverse and descending portions. An increase in the transverse diameter of the heart amounting to about thirty per cent. Blood and urine examinations gave negative results.

CASE III.—Hebrew, age 60, actor, applies for treatment for constipation and weakness. Family history: Father died at 70 from Bright's disease; mother at 90 of senility; one sister has chronic rheumatism. Has eight children, all in good health. Wife is troubled with sciatica; had miscarriages prior to marriage to patient.

Personal history: Severe attack of typhoid fever at 19 and made a good recovery; about 25 suffered for a

time with rheumatic pains in arms and side of neck. Had sciatica twelve years ago and was confined to bed for two months. Contracted both gonorrhea and syphilis when a young man. Had Wassermann tests made six and twelve months ago; both positive. Had salvarsan four months ago and thinks that he has felt better since. Has been chronically constipated for 25 years and has had to use laxatives constantly. Is subject to headaches, which are worse when he is most constipated. Some vertigo. Has shooting pains in top of head. Uses very little alcohol, no tobacco. Diet simple as a rule, uses a good deal of spices and condiments. Has nocturia four or five times, has to strain to start flow of urine and has a burning sensation in urethra. Has a diplopia which has existed for four or five years.

About five years ago sugar was found in his urine; treatment at Carlsbad relieved this and no sugar has been found during the past six months. He complains of a frequent dull aching pain in his back adjacent to the left scapula, which causes him a great deal of distress, especially when he stoops over. He also complains of pain in the precordial region which extends to left shoulder and down his arm; this is most apparent when quiet and is not aggravated by exercise. Has lost 20 pounds in past two years.

Physical examination: Weight 180, eyelids puffed, tongue coated, pyorrhea alveolaris. General nutrition very good; muscles flabby, skin anemic. Chest of nor-

FIG. 5.—Case III. Roentgenogram showing anterior view.

mal size, respiratory sounds harsher than normal. Cardiac dullness extends 10 cm. to the left and a out 6 cm. to right of midsternal line in second interspace. Apex beat in midclavicular line fifth interspace. On auscultation a systolic murmur is heard at the aortic area and is transmitted for a short distance to the left.

Abdominal reflexes absent, knee jerks normal. Left pupil larger than right, both reacting sluggishly to light and accommodation. No static ataxia.

Urine examination showed a trace of albumin and a few hyaline and granular casts. Blood examination showed a mild degree of anemia. Systolic pressure 130, diastolic 58, pulse pressure 72. The x-ray examination of the chest revealed an aneurysm of the descending portion of the aortic arch, with marked dilatation of the remainder of the arch, and an increase in the transverse diameter of the heart amounting to rather more than 25 per cent.

These three cases of aneurysm of the arch of the aorta affecting the first, second, and third portions, in which there is a low systolic pressure, associated with a high pulse pressure, cannot be accounted for by an insufficiency of the aortic valves. In the first case, post mortem examination of the heart showed intact aortic valves, in the other two cases there was no diastolic murmur such as is

found in aortic insufficiency. Consequently, the low diastolic pressure and high pulse pressure must be accounted for in some other manner.

In all probability, a considerable widening or weakening of the arch of the aorta has mechanically the same effect on the blood stream during diastole as do incompetent aortic valves; a comparatively large reservoir exists, into which the blood is suddenly forced during diastole, thereby diminishing the diastolic pressure and correspondingly increasing the pulse pressure.

All cases of aneurysm of the aortic arch are not accompanied by low diastolic and high pulse pressure, but where such pressures do exist and the signs of aortic insufficiency are not present, the possibility of the existence of an aneurysm of the aortic arch, we believe, should be considered.

WEAK FEET IN CHILDREN.

BY JACOB GROSSMAN, M.D.

NEW YORK.

CHIEF ORTHOPEDIST, GERMAN POLIKLINIK; ORTHOPEDIST, LEBANON HOSPITAL, O. P. D.; ASSISTANT ORTHOPEDIST, NEW YORK POST-GRADUATE HOSPITAL.

FROM a clinical viewpoint weak feet in children do not differ materially from those in adults; still the history and the symptoms in the former are so different from those in the latter that a special description of the condition is warranted. Search of the literature reveals that this very important ailment in children is little emphasized. Many children are permitted to go through childhood handicapped by weak feet which in the majority of cases would respond to very simple corrective measures. Teeth, eyes, ears, and the remainder of the body are carefully examined for pathological conditions, but the feet which are as vitally important in the proper development of children as any of the above are passed over superficially or entirely overlooked. After a very careful study of an extensive number of cases of weak feet in adults, there is no doubt in the mind of the writer that in the vast majority of them the predisposition to weak feet, or the weak feet themselves, can be traced back to childhood.

In the offspring of parents in whom there is a history of weak feet I have not infrequently found existing weak feet or a predisposition toward them. It is not uncommon to find a mother bringing to the clinic several children, all suffering from weak feet, and the many instances of familial weak feet that I have encountered in the clinics suggests the possibility of an inherited predisposition in those cases.

In infancy and early childhood the feet appear to be flat; this flatness is not permanent, but is the result of the osseous structures of the arch being surrounded by pads of fat. This has been proven by examination of frozen sections of specimens. As the child grows and becomes thinner the fat gradually disappears and the arch becomes more conspicuous. This change usually begins after the second year of life and is completed after the third year. Footprints of infants up to three years of age give a flat impression; these flat impressions are normal for that period. After the third year the impression is the same

as that found in the normal adult foot. As a rule, however, the imprints do not reveal the true clinical picture. Patients suffering severely may have a normal footprint, while other patients having a very flat imprint may suffer very little or not at all.

ward upon the oblique articulating surface of the os calcis, at the same time calling forth an outward rotation of the astragalus. This intended torsion is communicated to the other bones, resulting in a turning outward of the foot. The

FIG. 1.—Non-spastic weak foot; note the eversion of the heels and heel cords, more marked on the left side

Healthy children when left to themselves usually begin to creep during the seventh and eighth months. This should by all means be encouraged, as it meets the natural requirements and trains the bones, joints, and muscles to bear weight later on. After this creeping period comes a more trying period, that of walking. The transition from the former to the latter should be a natural one. Where children are taught to stand on their feet

FIG. 3.—Sol. P., non-spastic weak foot

inner border of the astragalus endures more weight, the os calcis is turned outward, and we have a weak foot. Hence it is safest to permit children to begin to walk when they themselves so desire. Premature walking aided by artificial appliances or devices is harmful and unnatural and should therefore be avoided.

Etiology.—Weak feet occur more frequently in females than in males. It is quite a common condition before the thirteenth year of age is reached. The condition may be congenital or ac-

FIG. 2.—Same as Fig. 1, front view.

too early the untrained muscles, bones, and ligaments yield to the overweight; deformities of the foot are produced that may lead to the marked degree of deformity which we see in flat foot. The weight forces the astragalus forward and down-

FIG. 4.—Same as Fig. 3, front view.

quired. Congenital weak feet are sometimes found in combination with club feet. There is a tendency to pes valgus deformity in a certain percentage of new-born infants. A marked flat-foot deformity is not of frequent occurrence. The

dorsum of the foot during the embryonic stage is pressed against the leg and retained in that position. The feet of the newborn persist in this attitude of rest for a long time. This should not be mistaken for a pathological condition, as time

FIG. 5.—Weak foot associated with genu valgum, note the marked eversion of both heels and heel cords.

elapses the position of the feet in the majority of infants assumes the normal relationship to the legs. Should this attitude of the feet persist it can then be considered to be a case of congenital weak feet. In some of these cases the sole of the foot is flat; in others it is convex. The contours of the bones are visible under the skin. The peroneal, flexor, and dorsal muscles are shortened.

Predisposition to weak feet due to heritage must be considered. Many cases of weak feet are found to be present in the offspring where one or both parents have the condition. I have been strongly impressed with the frequency with which I have been able to demonstrate weak feet in brothers and sisters, as well as in one or both parents.

Acquired weak feet may be the result of or occur in conjunction with many conditions. In children with a general muscular relaxation, weak feet are very often present as the result of muscular weakness. Infantile paralysis in which the

FIG. 6.—Same as Fig. 5, front view

tibialis anticus is involved is the cause of paralytic weak feet. Rickets, especially with genu valgum, is often accompanied by a valgus of the foot. Injuries, among which fractures are the main ones, often give rise to the traumatic weak

foot. Occasionally the trauma is the result of a wagon wheel passing over the foot, or in other instances a weight falls upon the foot. Overweight is a common cause. Prolonged rest in bed from any of the infectious diseases, inflammatory

FIG. 7.—Weak foot from paralysis of the tibial muscles.

or infectious conditions in or around the ankle or foot, may predispose the individual to weak feet. It is true that in a number of cases the history of a predisposing or exciting factor cannot be ascertained. It is a difficult matter to determine the cause in these cases.

Poorly fitting shoes in children can in the majority of cases be eliminated as a causative factor in the production of weak feet. The shoes made for children are very good ones; they have broad toes and are roomy enough to allow for free action of the small muscles. Not only should the shoe be roomy, but stockings should also fit well. Stockings which are too tight or small will cramp the foot and interfere with the proper action of the muscles of the foot, in that manner predisposing the child to weak foot.

Pathology.—In the average case the foot appears to be turned outward below the ankle and the axis of the lower leg presents an outward devi-

FIG. 8.—The anterior tibial line. A, normal. B, in a case of weak foot.

ation in the plane of the ankle. The internal ankle may project from a slight to a considerable degree. The arch of the foot is not only lowered, but in severe cases appears to be convex, the bulging resulting from constant lowering and outward

turning of the head of the astragalus and scaphoid. The inner border of the foot appears to be much longer than the outer.

Symptomatology.—Subjective: In those cases resulting from a specific cause, such as infantile

FIG. 9.—Method of strapping weak feet.

paralysis, injury, an infectious process, etc., this history is elicited. Some children have a limp, some fall, others turn the ankle; in other cases the children walk with the toes pointing outward. Again there are cases where there are no subjective symptoms. The children are brought to the clinic because they always wear their shoes out on the inner borders of the soles and heels. In these cases the shoes are not only worn out on the inner borders of the soles and heels, but the inner surface of the last of the shoe is distinctly prominent and bulging, the result of the constant pressure of the displaced astragalus. Occasionally the children will complain of pain in one or both legs, the location of which is variable. At times it may be referred to the inner border of the foot, but more often to the calves of the legs. Other children tire easily and want to be carried continually. In a number of cases the children are brought to the clinic to be treated for a sprain or fracture of the ankle and the presence of weak feet is discovered for the first time. In these cases history of any of the aforementioned subjective symptoms cannot be obtained. The mothers are unaware of the fact that their children have weak feet.

Objective: The gait of these children is awkward. They walk upon the entire sole of the foot. The toes turn out and the soles and heels are worn out on the inner border. The most important objective symptom is the eversion of the heels and heel cords. In the normal foot the heels and heel cords are either parallel to or converge slightly toward a line drawn perpendicularly through the center of the trunk and continued downward to the ground. In weak feet there is a tendency for the heels and heel cords to be everted, to roll away from this midline. This eversion varies with each case. In mild cases it

may be very slight, while in the more severe types it is very marked. With this eversion there is a lowering of the arch as a whole. In the early cases disturbance in the osseous structure of the arch is not discernible; nevertheless there may be a slight stretching of the ligamentous and muscular structures. As the condition progresses the ligaments and muscles become more and more stretched until finally there is complete collapse of the keystone of the arch and the sole of the foot is applied flat to the ground, resulting in a pes planus. With these changes the eversion of the heels and heel cords keeps pace, so that marked eversion is always present in these advanced cases.

The evidence derived from an impression of the sole of the foot fails to give us the true status of affairs. Cases suffering very mildly or not at all may give a normal foot impression. In very young children it is of no value, as all the impressions are flat, due to the pad of fat which surrounds the osseous structure of the arch. It is of no value in determining which foot is more profoundly affected. We have found in our experience that very flat impressions were present in feet which gave very slight symptoms, and normal impressions in feet which produced very severe pain and disability.

The displacement of the anterior tibial line is another valuable aid in diagnosing weak feet. Normally the anterior tibial line falls over the first or second toes; in weak feet it usually falls toward the inner side of the big toe or over the center of the inner border of the foot. The anterior tibial line is found by following a line passing along the crest of the tibia and continuing it along the dorsum of the foot.

Spastic or rigid weak feet are rare in children. Occasionally one may be encountered. In these cases there is limitation of the range of motion due to the spasm of the muscles on the dorsum and outer side of the foot; the spasm resulting from shortening and contraction of these muscles owing to the persistent attitude of valgus.

Treatment.—Prophylactic: A great deal can be accomplished in the prevention of weak feet. The feet of children should be examined as frequently

FIG. 10.—External flange of the Whitman brace.

and carefully as the eyes, teeth, or mouth, and where there is any suspicion of weakness or a tendency toward weakness proper measures should be instituted.

The feet of small children should not be forced

or pressed into shoes. The children should be given frequent opportunities to walk in their bare feet. This allows free action of the muscles and hence strengthens them. Creeping should be encouraged as much as possible. Infants should be placed upon their abdomens as soon as practicable. The desire for locomotion will soon induce the children to creep and frequent opportunities will eventually accustom them to this new achievement. This creeping period should not be suppressed. Permitting the child to sit too early will encourage the child to slide over the floor on the buttocks. This will delay creeping, and should not be permitted.

The period of creeping should be changed by the child into one of walking. Only when a child of its own accord attempts to stand up and walk, holding to surrounding objects, should it be permitted to do so. To force them to walk prematurely, with the aid either of nurses or walking appliances is objectionable. All such devices are impracticable and unnatural. Hastening the commencement of locomotion predisposes children to weak feet.

Regardless of the presence or absence of weak feet, broad-soled sandals for the younger children

FIG. 11.—Internal flange of the Whitman brace.

and shoes for the older ones should always be recommended. These allow of free and unrestricted action of the toes and small muscles of the fore part of the feet.

Curative: In very young children proper sandals or shoes alone will usually overcome weak feet. The sandals or shoes should be broad-soled, they should have a lift of an eighth to a quarter of an inch on the inner border of the soles and heels. The thickness of the lift depends upon the amount of valgus present. The mild cases should have a lift of an eighth of an inch and the severer ones a quarter of an inch. Lace shoes are preferred to those that are buttoned.

If after a reasonable length of time the shoes fail to relieve the condition braces must be added to the treatment. The brace which has been found to be very efficient is the Whitman brace. The brace is modeled upon a plaster cast of the foot taken while the foot is held in the fully corrected position. It fits the arch of the foot accurately, extending forward to the ball of the big toe, outward round the outer border of the foot and backward to just in front of the tuberosity of the os calcis. On the inner side it is enlarged

upward and extends to a point one-half inch below the internal malleolus. With a properly made brace the foot should rest upon its normal bases of support, *i. e.* the under surfaces of the heads of the first, fourth, and fifth metatarsal bones and the tuberosity of the os calcis. These braces should be accurately fitted and each should be made for the individual who has to wear them.

The method of taking the cast of the foot which the writer has found efficient is a very simple one. The patient sits upon a chair with his foot upon a second chair of the same height. On this chair is placed a small cushion covered with a towel on which talcum powder has been sprinkled. Plaster of paris is then mixed with water to form a thick cream; a piece of gauze is then steeped in the plaster-of-paris cream and laid upon the towel, underneath the foot, so that the outer border of the sole rests upon it along a line about an inch from the edge. The foot rests upon its outer border and is held at a right angle to the leg. The gauze is then wrapped around the foot, covering in the heel behind and extending as far forward as the cleft between the toes; it should reach up above the internal malleolus, but should not overlap the dorsal surface to any extent. This covering is allowed to set and when the plaster is hard there is no difficulty in removing the foot from it. A fresh plaster cream is now made. The mold is well powdered and the plaster cream is poured into it and arranged so that it fills the mold, but does not project beyond it in any direction. When the plaster has set the sides of the mold are forced aside, the cast is removed and properly carved and marked for the instrument maker.

The brace is made of thin steel or aluminum alloy and should extend forward to the line of the metatarsophalangeal joint of the great toe and backward to the center of the heel; on the outer side it grasps the foot just behind the prominence formed by the fifth metatarsal bone and on the inner side of the foot it extends upward to one-half an inch below the internal malleolus. It should fit the cast accurately, except over the heel, where it should be slightly flattened so as to make it steadier. It should be worn for short periods at first, the length of time being gradually increased as tolerance is established. The length of time the support is necessary varies with the condition of the patient and the strain to which the feet are subjected. The brace should be corrected from time to time so as to conform with the changes taking place under its use.

In older children we have slightly different conditions with which to contend. Pain, rarely present in the younger children, is one of the common complaints of older ones. For the acute pain strapping offers the quickest relief. The method we use has proved very satisfactory. One end of a strip of adhesive plaster about eight inches long and one inch wide is applied to the outer side of the ankle just below the external malleolus; the foot is then adducted as far as possible and the plaster drawn tightly beneath the sole up the inner side of the arch and the leg, being kept in this position by one or two strips about the calf. Strips about three-quarters of an inch wide are

then applied in a figure-of-eight manner about the arch and ankle, beginning at the back of the heel and extending as far forward as the base of the first metatarsal bone. Strapping should be done twice a week and continued until the pain has subsided. Where necessary, shoes and braces should be recommended.

When children are old enough exercises have proven valuable adjuncts in obtaining a successful issue. The following exercises have been found to be very efficient.

1. Tip-toe exercises: the patient places the limbs in the attitude of moderate inward rotation, raises the body on the toes to the extreme limit, the limbs being fully extended at the knees, then sinking slowly, resting the weight on the outer borders of the feet in marked varus, repeating about twenty to thirty times.

2. Walking in bare feet.

3. Walking on the fore part of the foot.

4. Grasping motions with the toes, exercises with foot weights.

5. Bicycling has also proved of value and should be highly recommended.

These exercises should be practised twice daily and should not be carried to the extent of tiring the patient.

In a number of cases operative interference is indicated. This is especially so in those cases due to infantile paralysis and congenital deformities.

If after the period of spontaneous recovery has elapsed paralysis of the tibialis anticus has not been overcome, operation may be necessary. The operations which have proved satisfactory are tendon transplantation and tendon fixation. These operations are too well known to require detailed description. Suffice it to say that they should be employed where the indication exists.

Achillotomy followed by proper after measures should be resorted to in those cases in which the tendo Achillis is contracted.

Arthrodesis, removal of a wedge-shaped portion of the tarsus, bone grafts, have all been advocated. Fortunately these operative procedures are not commonly required.

Summary and Conclusions.—1. Children should be examined for the presence of weak feet.

2. Special prophylactic precautions should be taken in children from whom a history of the presence of weak feet in one or both parents is obtainable.

3. Feet in very early childhood are apparently flat. They should not be considered as pathological unless the flatness persists after the third or fourth year of age.

4. Exercises, such as creeping for the infants, and those previously enumerated for the older children, are very beneficial and should be encouraged.

5. For acute pain rest and strapping are indicated.

6. Proper precautions should be taken in infantile paralysis in which the tibialis anticus muscle is involved. In knock-knee the shoes should be raised from one-eighth to one-quarter of an inch on the inner side of both soles and heels, so as to overcome the tendency to valgus which occurs frequently in this condition.

7. When in spite of proper precautions and prophylactic measures weak feet occur, a support becomes necessary; the Whitman brace has proved to be the most satisfactory.

8. The method above recommended for taking the cast of the foot has the following advantages. First, it is a very simple one. Second, with the method described the foot of the patient is very easily controlled. Those who have had experience with children know how difficult it is to control them until the plaster has set. With this method they are very readily controlled. Finally a more accurate cast of the foot is obtainable.

9. Too much importance should not be placed upon the evidence obtained from foot prints, as in the majority of cases they are misleading and do not give us accurate data of the pathological condition present.

10. Eversion of the heels and heel cords is the most constant diagnostic feature in weak feet.

11. By the application of the foregoing prophylactic measures in every case in early childhood, regardless of the presence or absence of weak feet, suffering, disability, and weak feet in adults will be kept at a minimum.

1051 BOSTON ROAD.

LOCALIZING POSTERIOR GONORRHEAL URETHRITIS.

BY HENRY J. MILLSTONE, M.D.,

CHICAGO, ILL.

THE frequency with which the posterior urethra is involved in our gonorrheas is still a much disputed question. To give the figures of the various authorities would be superfluous, but the conclusion that can be drawn from their observations is that rarely does the posterior urethra escape the insults of the gonococcus. Their figures vary from 60 to 95 per cent.

FIG. 1.—Endoscopic view of the posterior urethra. 1, pus coming from the prostatic duct; 2, ejaculatory duct; 3, prostatic duct; 4, prostatic sulcus; 5, sinus pocularis (utricle).

It is not the purpose of this paper to discuss the various reasons for this condition, but it certainly does occur many more times than it rightfully should. Probably the greatest factor producing a posterior urethritis is the promiscuous and unintelligent use of the urethral syringe, and the sooner we disarm our patients of this dangerous instrument the sooner will the percentage of posterior gonorrheal infections decrease.

Were the posterior urethra lined with smooth mucous membrane, chronic gonorrhea would be practically unheard of, but the fact that it gives off various diverticula in the shape of lacunæ, crypts,

*Read before the Staff, Washington Park Hospital, Feb. 9, 1918.

glands, and their ducts, makes it possible for the gonococcus to be harbored for years undetected in these hidden cesspools. These complicated avenues are the chief cause of our inability to make an intelligent diagnosis, and their anatomical complexity makes them practically impossible of therapeutic approach.

A mere glance at the anatomy (Fig. 1) will give us an idea of how intimately these various structures are associated. The verumontanum springs from the floor of the prostatic urethra, much as the uvula projects from the soft palate. It is of firm consistency and composed of definite acini (Rytina). Its bulging into the urethra is mainly due to the pushing forward of the utricle and ejaculatory ducts. On the summit of the verumontanum and a little anterior is the utricle (vagina masculina) which is the embryological remains of the obliterated Mullerian ducts. This is a blind pouch and makes an admirable focus for the harboring of the

pus. While often this is the case, still it may be possible for only one of these structures to be infected. The frequency with which the various structures are infected in the posterior urethra is also a much disputed question, but probably the greatest in frequency are the prostatic ducts on account of their anatomical position, that is emptying into these lateral gutters into which pus easily gravitates. Probably next in frequency is the utricle, next the seminal vesicles, and lastly Cowper's glands. The seminal vesicles are probably spared so frequently from the fact, as I have stated, of being surrounded by a sphincter and guarded by a connective-tissue door. The ejaculatory ducts are closed and in a state of tonic contraction, opening only at the height of the sexual orgasm.

With our increased knowledge of intraurethral surgery, it can readily be seen why a diagnosis of the infected structures is essential. A rational diagnosis is not only important from the standpoint of treatment but will also aid us materially in arriving at some prognostic conclusion, for after all this is the point which so materially concerns our patient, for they will continually bombard us with "Can I, and how long will it take before I am cured?" It is not the purpose of this paper to discuss these points but I merely wish to bring out a procedure which has been of great service to me in localizing the pathology in the posterior urethra.

I would only mention that we are all agreed that we must not use instruments in the urethra before the gonorrheal infection is perfectly quiescent and the patient has had sufficient opportunity to build up a local tissue and general resistance, which is usually about three months. Before the introduction of the urethroscope we relied entirely upon rectal examination for the diagnosis of infections of the seminal vesicles, prostate, and Cowper's glands. In 1890 Fuller insisted on a greater recognition of this procedure,

which is certainly neglected by most men. Much can be learned from rectal examination in the male, and certainly should be instituted as a routine procedure in all our chronic gonorrheics and in other obscure conditions in the male, for the posterior urethra is certainly a prolific source of focal infections. (Billings.)

The method I have been using for localizing a posterior gonorrheal infection is very simple, and while the illustration (Fig. 2) is self-explanatory a few points as to the technique will not be amiss.

Technique.—First. Massage prostate, vesicles, and Cowper's glands, followed by a warm irrigation of boric acid solution. The purpose of the massage is to squeeze out any inspissated debris which may be lying in the ducts and occluding them. The irrigation washes out the entire urethra. A Barnes' bag (medium size) previously lubricated is curled up and inserted into the rectum. Attached to the Barnes' bag is a rubber bulb taken from any blood pressure instrument which makes it easy to control the air. The patient is now placed in a cystoscopic position and the urethroscope passed into

FIG. 2.—The posterior urethra: 1, internal sphincter; 2, verumontanum; 3, sinus pocularis; 4, prostate; 5, ejaculatory duct; 6, ampulla of vas; 7, ureter; 8, seminal vesicle; 9, vas; 10, symphysis pubis; 11, triangular ligament; 12, duct of Cowper's gland; 13, external sphincter (cut-off muscle); 14, Barnes' bag in rectum.

gonococcus. On the acclive or the anterior surface of the verumontanum lying usually below and one on each side of the utricle are the openings of the ejaculatory ducts which have a definite involuntary-muscle sphincter guarded by a tit of connective tissue (Belfield). On each side of the verumontanum is a gutter known as the prostatic sulcus, into which empty about fifty (Woolsey) small ducts (prostatic ducts), invisible to the naked eye when seen through the endoscope. Between the two layers of triangular ligament are Cowper's glands whose ducts pierce the anterior layer of the triangular ligament and empty into the bulb of the anterior urethra. All of these structures occupy an area about three quarters of an inch long and if we bear in mind that the posterior urethra is a closed tube, it is almost impossible to conceive how any of these structures can escape being infected when the posterior urethra is involved and literally bathed

the posterior urethra so that the verumontanum pops into the fenestra which is placed on the heel of the instrument. I have obtained splendid results by using Swinborne's urethroscope. The area of the verumontanum is now swabbed dry with cotton applicators. One now attaches the eye piece which may be magnifying, which brings out the details better. We can now see the utricle, ejaculatory ducts, and lateral sulci. Ordinarily the prostatic ducts cannot be seen; however, if diseased, they are patent and may be surrounded by an inflammatory zone. The bag in the rectum is now inflated. This applies pressure or mild massage to the seminal vesicles and prostate, and if pus is present it will be seen exuding from the ducts of these structures. If nothing comes out of these ducts we may gently probe them with a fine filiform and inflate our bag again. To observe Cowper's ducts one gently withdraws the instrument until it can be felt to escape the grasp of the external sphincter. The heel of the instrument is now in the bulb and one again inflates the bag and looks for pus. Ordinarily it is not possible to see these ducts, but when the gland is infected they are usually patent and may be surrounded by an inflammatory halo.

With this procedure one may arrive at a proper diagnosis and render an intelligent prognosis, and the method is also applicable for treatment. It may be possible to obtain pus from these structures for an autogenous vaccine and through a proper sized cannula medicament may be carried to the structures, or we may insert a fine wire in the utricle, prostatic ducts, and Cowper's ducts and pass our Oudin or d'Arsonval current through them, completely destroying them. The current should never be passed into the ejaculatory ducts for reasons which are self-explanatory.

EUGENICS: ITS RELATION TO MENTAL DISEASES.

BY JOHN JOSEPH KINDRED, M.D.,

ASTORIA, L. I., N. Y.

EUGENICS may be defined as the science of race improvement through the application of the laws of heredity. In the words of Sir Francis Galton, who laid the foundations of this science in the year 1865, "Eugenics is the study of the agencies under social control that may improve or impair the racial qualities of future generations, physically, mentally, and morally. The aim of eugenics is obviously the production of a more healthy, more vigorous, more able humanity, and to bring as many influences as can be reasonably employed, to cause the useful classes to contribute their full pro-

portion, or even more than their full proportion, to the next generation and to cause the useless, vicious, and constitutionally diseased and degenerate classes to contribute less than their proportion to the coming generations."

Both the study of eugenics and heredity must be predicated on some consideration of the origin and evolution of the human race. Whatever may have been the origin of the race, whether from ultimate protoplasm or otherwise, racial evolution physically, mentally, and morally during thousands of years, as related to the study of human heredity and eugenics, is of absorbing interest. We know how slowly but triumphantly this complex evolution has gone on, until man and his achievements, notwithstanding human defects and limitations, during the present and recent centuries have become marvels of efficiency.

Eugenics may be spoken of medically as a prophylactic against the continuation of race impairment. As all prophylaxis or preventive medicine is necessarily correlated to the treatment of all racial ills, it follows that we as physicians and psychiatrists may well concern ourselves with the solution of every practical phase of this whole problem as it exists to-day, due to the neglect of eugenic rules, emphasizing particularly the problems here involved of a vast number of preventable mental and other diseases.

The laws of eugenics are based on the laws of heredity, but the application of these laws is different in eugenics. As underlying the laws of heredity we shall merely refer to some of the conclusions of "natural selection" and "survival of the fittest" as an essential factor in the origin of species and of other related laws of evolution as laid down by Charles Darwin, Alfred Russell Wallace, and others, remembering, as Darwin says, that this doctrine forms the only rational explanation of the laws of the gradual development of the innumerable forms of living things and their enormous powers of increase.

The Darwinian law of "the survival of the fittest" is greatly modified in the human race because mankind is exclusively possessed of intellect, which Alfred Russell Wallace, the contemporary of Darwin, calls "the influx of some portion of the Spirit of the Deity, a living soul, into man," which inspires him to conquer in the struggles of life and to help himself and others in dangers, prostrating illness and in providing food, shelter, and comforts, in circumstances where the lower animals could not thus provide. Our modern hospitals and other charitable, educational, protective and humane institutions for conserving the life and welfare of all, particularly the helpless, and for the development of the higher mental and moral faculties, are a sublime illustration of how man's intellect and moral nature differentiates him from the lower animals.

To develop and extend these high human standards of Wallace it is necessary to remedy the unchecked, blind workings of the laws of "natural selection" by what might be called "artificial selection."

In connection with the laws mentioned and the parent sciences of eugenics, namely biology and sociology (to which latter reference will be made

later), and as fundamentally related to heredity and eugenics, let us refer briefly to some processes in reproduction and embryonic life, and show how the splitting into doubles of the chromosomes in the process of fertilization of the female egg by the male sperm cell and the consequent mixing of the chromosomes of the parents result in a mixture of parental traits and characters,—these chromosomes being termed the determiners of heredity, which carry to the offspring the parental qualities, through the mechanism of the nuclear divisions of the sex cells. This mixture of the nuclear chromosomes, called *amphymixis*, probably has other important functions besides that mentioned, creating variations, particularly the larger variations called mutations, which “natural selection” could take hold of; it also has the function of eliminating certain variations which are possessed by only one parent, constantly tending, therefore, to bring the individual progeny back to the type of the species.

Dr. C. B. Davenport, who has contributed largely to this subject, in his several books on “Eugenics and the laws and methods of heredity in man, the lower animals and the vegetable world,” lays down important generalizations, the first of which is “When a determiner of a characteristic is absent from the germ-plasm of both parents, as proved by its absence from their bodies, it will be absent in all of their offspring, this being called nulliplex. Therefore, in order to predict the result of a particular mating, it is necessary first to know which similar unit characteristic both of the parents lack, which they both possess, and whether the characteristics are due to the presence of a determiner or to its absence. This can, in part, be determined experimentally or inferred from pedigrees.” It follows, according to Davenport, that we do not inherit from our parents, grandparents, or collaterals but that related individuals have some common characteristics because developed out of the same germ-plasm with the same determiners. A child resembles his father because he and his father are developed from the same stuff. Both are “chips from the same old block.” Some determiners carry characteristics that are positive and others characteristics that are negative, which latter depend upon the absence of a determiner. Thus the presence of brown eyes depends upon an enzyme that produces the sepia-colored pigment, while blue eyes depend upon the absence of such an enzyme. It is not always easy to say in advance whether a given characteristic is positive or negative, as for instance, the long hair of angora cats, of sheep, or guinea-pigs is apparently not due to a factor added to conditions that would produce short hair, but rather to the absence of a determiner that stops the growth of hair in short-haired animals.

If both parents have the character as a single or simplex character, then the two determiners will meet in one force of the union of egg and sperm, the two simplex characters will both be absent in one-fourth of the progeny and only one simplex character will occur in half of the progeny.

If one parent has the characteristic simplex and the other duplex, then half the offspring will have it simplex and the other duplex. The inheritance or non-inheritance of some of these traits like hair, the color of the eyes, etc., which so well illustrates

the precision of the modern science of heredity, though originally considered to be immaterial to well-being, are important, if the observations of Major C. E. Woodruff, M.D., that pigmentation protects individuals from the injurious effects of the tropical sun's rays are true.

The combinations or blending of these characteristics is so complex, and has such an infinite variety of results to the human being growing from the fertilization of the ovum (a fertilization that leads to but one out of thousands of possible combinations) there is a plain duty to all who may become parents to keep themselves in the best possible condition physically, mentally and morally.

The germ-plasm or germ cells are differentiated from the body or soma cells very early in the course of development and reside in the ovaries and testes, being in a measure out of relation to the body cells and leading a relatively independent existence, except for the fluids surrounding them and from which they derive nourishment. This gives rise to *the theory of the continuity of the germ-plasm*, meaning that they, the sex cells, carry on through all generations the purely hereditary factors, from individual to individual, practically uninfluenced by what may occur in the body at large, so that regardless of such accidents to the body, as for example, the loss or mutilation of a limb, or other similar changes or the acquirement of some special skill in one direction, the germ cells are uninfluenced and carry on from generation to generation only what they originally contained.

The inference from this theory of the continuity of the germ-plasm is that characters acquired by individuals in their lifetime, or characters possessed by the individual but not inherited by them cannot be transmitted. Weismann and his school insist that the inheritance by the offspring of the acquired characters of the parent is inconceivable. They admit that the germ-plasm itself possesses all the marvelous potentialities which are necessary to account for the highest development of mankind. If Weismann is right in his contention that no acquired characters can be transmitted to posterity then all of the achievements of our education, training, and civilization, which have been going on during thousands of years and which have been so rapid in their strides since the invention of the printing press, are completely lost, so far as they affect the innate character of posterity. While all authorities agree with Weismann that the so-called innate or inborn traits are sure to be transmitted, many authorities believe that the effects through many generations of all these acquired characteristics so react on the body and mind and moral nature of human beings that they result in corresponding variations, which have commenced long ago, as a consequence of these forces.

The Lamarckian theory insists that structures came into existence or went out of existence by the results of use or disuse and that the effects in either case were transmissible by inheritance.

The Neo-Darwinian theory, as stated by Dr. J. William White (who has contributed so much of value to this whole subject in the two volumes on “Mental and Nervous Diseases,” edited by him and Dr. Smith Ely Jelliffe), explains the effects of use and disuse only as bringing out or suppressing

certain potentialities. "The muscles of the blacksmith's arm grow larger by use, but they could not grow larger as a result of use if there were not resident within them the potentiality to increase in size, and it is this potentiality the Neo-Darwinians would say, that is passed on in the germ-plasm, and nothing more. Such changes as the unusual growth of the muscles of the blacksmith's arm, however, should not be lost sight of as evidencing the very material way in which the individual may be influenced."

One of the most absorbing features of the study of eugenics and heredity is to follow the inheritance by children of the infinite variety of mental, moral, as well as physical traits of their ancestors. This brings us to that phase of the subject known as variations from type, which has already been referred to in the mixing by the chromosomes in the germ-plasm.

Variations or modifications must be what is called determinate and not haphazard, as nothing in nature may be assumed as occurring, except in accordance with natural law. The variations caused by the presence of poisons like alcohol or diseases like syphilis, of the stunting effects, during embryonic life and of the lack of proper food, constitute a variation from the type entirely different from those variations here referred to as being determined by the mixing of the parental chromosomes or determiners.

The determination of variations by environment, religious and moral training, and all the educational and civilizing influences during thousands of years form an interesting part of this study as to the exact effects of which the highest authorities have radically differed, as has been pointed out in the brief reference to the theories of Weismann, Lamarck and the Neo-Darwinian theory.

The Mendelian theory of inheritance is based on the conclusions from experiments with plants chiefly, that there are certain characteristics of the individual called unit characters which are represented by the determiners of the germ-plasm, these being conceived to be definite material entities carrying special characters that cannot be blended when used in the true sense of that term, but must be an inheritance dependent upon the segregation and grouping of the determiners. Mendel formulated to the satisfaction of his followers with mathematical precision the ways in which inheritance would manifest itself by determining all the possible combinations in which these determiners would group themselves. In studying the Mendelian law it is essential to remember that certain determiners are dominant and certain others are recessive; as for example, if a flower contained a determiner for the red color and a determiner for the white color and the red determiner was dominant, the color would be red, but if the germ-plasm contained a white determiner which is recessive, this recessive determiner, white, would produce a certain number at least of white progeny. If a given determiner comes from one parent only, the heredity is simplex, while if it comes from both parents it is duplex. If there are no determiners on either side for a given quality, it is absent and the heredity is said to be nulliplex. Theoretical expectations and actual findings as related to the Mendelian theory,

do not, as is to be expected, always show an exact correspondence but are an expression of probable chance.

One of the interesting conclusions of Mendel is that a pure bred may be derived from a hybrid in one generation, and that the hybrid of a pure bred produced by a long series of hybrid individuals is just as pure as the pure bred which has never had a hybrid ancestry. Another important consequence is, that among the offspring of the same parents some individuals may be pure bred and others hybrid. Community of parentage does not necessarily denote community of characteristics among the offspring.

Among the high American authorities, who have made valuable contributions supporting the idea that the Mendelian proportions obtained in the inheritance of epilepsy and feeble-mindedness, are Weeks and Davenport, in their notable work on "Epilepsy and Feeble-mindedness," and in which they present research and a large number of pedigrees well worthy of the serious attention of students of this subject.

It must be borne in mind that Mendel's interesting experiments were confined to the hereditary manifestations in flowers and plants and certain of the lower animals, and that while they are full of suggestiveness they did not go far enough to justify us in saying that all of his conclusions were applicable to heredity in human beings. Bateson, a leading English authority, says of the Mendelian theory that "we have the certainty that it extends far and that there are ample indications for supposing that we should probably be right in assuming that it covers most of the features whether of the mind or of the body"; but he doubts if the Mendelian proportion exists as applicable to the inheritance of mental and other diseases. F. W. Mott, to whose great work we shall refer later, expresses substantially the same view.

In harmony with the Mendelian experiences are the following lines from Goethe:

"Stature from father, and the mood
Stern views of life compelling;
From mother I take the joyous heart
And the love of story telling.

"Great-grand sire's passion was the fair—
What if I still reveal it?
Great-grandmam's pomp and gold and show,
And in my bones I feel it.

"Of all the various elements
That make up this complexity,
What is there left when all is done
To call originality?"

Goethe's version of his own traits derived from inheritance suggests that the characters from either parent exist side by side, like the single units in the ordinary mosaic or tiles in a tiled floor.

Galton's "Law of Ancestral Inheritance" has distinct reference to the mechanism of the final splitting up of the chromosomes and their union (not blending) with corresponding portions of the opposite sex, so that each new germ cell contains chromosomes, some of maternal and some of paternal origin, each with its contained determiners, or the transmitters of each separate character of one parent or both parents. This law, which is satis-

factory as a whole, was formulated by Galton, not to apply to individuals, but to express the general result when applied to a large number of individuals in many generations; and it holds true only if we consider the chromosomes as being uniform in structure and the part going to form each nucleus being equal not only in quantity but quality. Galton showed that the older and more fixed a characteristic is, the more liable it is to the law of "filial regression." Galton's law compared with Mendel's applies only to masses of people and not to individuals. Galton said, "though one-half of a child may be derived from either parent yet the child may receive a heritage from a distant ancestor, which neither of his parents possessed. Galton's statistical inquiry into good and bad tempers in a family tend to show that they exist in different members at haphazard; another tends to assimilate them in such a way that they shall be all good or all bad; a third set tends to divide families into contrasted portions.

The approximate formula of Galton and others for the inheritance of ancestral qualities, stated briefly, is that a man inherits his qualities—physical, mental, and moral—one-fourth from each of his parents; one sixteenth from each of his grandparents, and one sixty-fourth from each of his great-grandparents; and it has been well said that the one remaining eighth in the final make-up of a man comes from "an unknown and certainly negligible part of gain through the father's activity; an unknown and negligible part of gain through the mother's activity; an unknown part, fortunately also negligible, of loss through the idleness or non-development of each; an unknown and doubtful change through pre-natal influences received through the mother; the whole reduced by untoward influences, many or few arising from transmission or failure in early nutrition, and to be modified in every part by the fact that he is a man."

"But these fractions indicate only potentialities. These make up the architect's plan on which the man is to be built. The plan admits of much room for deviation. Every wind that blows will change it a little. These elements themselves are of varied character. They do not belong together nor are they held in place, so far as we know, by any 'ego' except that made by the cell alliance on which they depend. Some of these elements the experiences of life will tend to reduce or destroy. Some of them will be systematically fostered or checked by those who determine the man's early environment. The final details will be beyond prediction. The ego or self in the life of the man is the sum of his inheritance, bound together by the resultant of the consequences of the thoughts and deeds which have been performed by him and by others also. Thus each day in his life goes to form a link in the chain which binds his conscious processes together. The vanished yesterdays are the tyrants of tomorrow. The higher heredity is the heredity from ourselves."

Race improvement must rest on "selection," good or bad. In other words, a wise process of selection will determine the future welfare of the race. What are some of the fundamental factors in that selection or as it may be called "artificial selection" that would work practically for this desired result?

Obviously, as far as possible, because of their direct or remote influences environmental conditions should be made wholesome, and reference to this will be made following some suggestions to be made on improving the mating conditions of that large and educable class known as normal recessives—meaning of course, persons who are themselves normal but having in their bodies the certainty of transmitting certain diseases or the tendency to these diseases, to their offspring in the first or succeeding generations.

Preliminary to some suggestions in relation to the mating of recessives with taints tending toward insanity and the psychoneurotic states it is necessary to note that there are six combinations of mates with reference to insanity that give rise to the theoretical expectation of different kinds of offspring, as follows (according to Dr. A. J. Rosanoff):

(1) Both parents being insane all the children will be insane.

(2) One parent being normal but with an inherited insane taint from his ancestors, and the other parent being frankly insane; half the children will be normal and the other half will be insane; but even the normal children from such a mating will carry the taint of insanity in their germ-plasm and will be capable of transmitting it to subsequent generations.

(3) One parent being normal and of pure normal ancestry and the other parent being insane, all the children will be normal, but will all carry the insane taint in their germ-plasm.

(4) Both parents being normal but each with the insane taint from the ancestors, one-fourth of the children will be normal and not capable of transmitting insanity to their progeny; one-half will be normal but capable of transmitting the insane make-up; and the remaining one-fourth will be insane.

(5) Both parents being normal, one of pure normal stock and the other with the insane taint from his ancestors, all the children will be normal, but half of them will carry the taint of insanity in their germ-plasm.

(6) Both parents being normal and of pure normal stock all the children will be normal and entirely free from the taint of insanity.

Theoretical expectations and actual findings, as related to the Mendelian theory, do not, as is to be expected, always show an exact correspondence, but are an expression of possible chance. Dr. Rosanoff's tables in his article on "Heredity; In Relation to Insanity and Eugenics," relating to psychoneuropathic offspring and normal offspring, according to the Mendelian theory, are well worth studying and justify the conclusion, he thinks, that insanity is transmitted from generation to generation according to the Mendelian proportions.

These six possible combinations should always be borne in mind in our effort to solve the marriage and mating problem of not only those suffering with the frank symptoms of inherited insanity but those normals whose sane and high sentiments make them more difficult to deal with in this regard.

Sensational or drastic methods or of legislation are not here proposed to prevent normal recessives

from marrying or mating. The slogan to bring about a change of public sentiment as to the danger of unsuitable matings must be, "educate, educate." We should have by every possible means of publicity and education, the main truths brought out with regard to insanity, promulgated by physicians, by public speakers and lecturers, by ministers of the Gospel, by the school books on sexual hygiene and physiology, by means of popular articles in the lay and scientific publications, and by every other possible means.

Such a widespread campaign of education of the people as to the truths of heredity and eugenics, the means of race improvement, should be accompanied by plain warnings as to the danger of unfit matings and at the same time confidential, free medical advice to the poor should be provided by law, so that those interested would be stimulated and encouraged to discuss this question as widely as possible and to seek counsel and advice from physicians and others competent to counsel and advise them.

We have only to recall case after case in our own experiences and to look up some of the thousands of charts that are accessible, showing the lamentable consequences of such unsuitable matings, to be impressed that the final elimination of insanity and many other hereditary diseases by the education of this large class of normal recessives in this direction, would prove on our part and on the part of the nation, worthy of our best efforts and any expense. In working out the problem we must also have in mind how neuropathic and other tainted stock is developed by bad mating out of an original healthy stock and how even epilepsy, insanity, and neuropathic and psychopathic states have been thus developed through a number of generations, notwithstanding nature is always trying "to end or mend" by "natural selection," sexual selection—aided by anticipation—stock that has become degenerate. As illustrating the elimination of even epilepsy running through several generations of tainted stock, by suitable matings of the normal recessives of that stock, and also as illustrating the development of epilepsy, insanity, neuropathic and psychopathic states in previously healthy stock by matings with tainted stock, the hereditary charts and family histories prepared by F. W. Mott, an eminent English authority, are illuminating and suggestive along the lines of the object of my paper, which is chiefly, to present some practical unsensational suggestions that, if followed, would materially lessen the preventable race impairment that is now surely going on.

If we consider not only the economic loss, amounting annually to hundreds of millions of dollars, caused largely by inherited diseases, as represented in the dependent classes in the United States according to the last United States census (approximately over 125,000 insane; over 100,000 feeble-minded; 100,000 deaf and dumb; 100,000 blind; 100,000 in prisons; 150,000 in reformatories and industrial institutions; 75,000 paupers and in almshouses; 500,000 defective in intellect, hearing, and vision; over 100,000 sick, deformed and crippled; approximately 2,000,000 in hospitals, homes, etc., or a total of approximately nearly 3,000,000 dependents, in all these classes), but also

the loss to the race caused by the death of one-half million children yearly in the United States and fifty million children yearly in the whole world and the further enormous economic and racial loss caused by the fact that of the children who survive in the U. S. approximately 30,000 to 40,000 are born through such bad hereditary conditions and with such serious physical or mental defects that they are a burden to themselves and to society, which is more and more contaminated by them, we, as physicians, humanitarians, and economists realize the importance of doing our part to help in the solution of this difficult problem.

Can we define ours as a truly enlightened, highly civilized and efficient nation, in which one person in about every thirty-three must be classed as inefficient, defective, or dependent?

In the words of Kellicott, "the time is arriving (and I will add that in fact it has arrived), when we must begin to think of the future of our communities and nations and of our race, rather than to contentedly read of and meditate upon the great achievements of our past, or to parade with self-satisfied air through the glass houses of Anglo-Saxon supremacy. Even were we unthreatened (and I would add that we are now actually threatened) were we amply holding our own, the mere fact of the possibility of a natural increase of human capacity would make it a practical subject of the utmost importance. We may be sure that somewhere a nation will avail itself of such a possibility as the increase of inherent, native, latent, physical, mental and moral inheritance, and will tend to become strong and dominant people. Why should we not be that people?"

Appreciating the well accepted idea of the influence of environment and training, how shall we nurture, protect, and develop the approximate one-tenth of the human species who are to become the parents of the coming race, by environmental influences?

If the United States government can, by wisely expending, as it does, hundreds of thousands of dollars annually to eliminate diseases of cattle, of swine, and the spirochete disease in the horse (comparable to syphilis in the human race) why could it not with more humanitarianism and wisdom, spend greater amounts for the same and similar purposes to benefit human beings, whose physical, mental, and moral health must in the end be either the glory or downfall of the republic? Parenthood with the race is everything that makes for either progress or impairment and probably the more important element in parenthood is motherhood.

Are the federal and state health agencies doing their full duty to eliminate disease, particularly those diseases which by impairing the health of the mother during and before the child-carrying period, naturally impairs the health of the fetus, and the adult growing from the fetus? Surely our economic and sociologic good sense should teach us that the first essential in well-ordered society is to see that the slums, sweatshops, bad factory and industrial conditions, poisoned foods, poisoned moral surroundings, vicious environment and all that militates against the physical, mental, and moral health of the masses of the people, especially

the pregnant and nursing women, as well as the children and younger people, should be intelligently and rigorously stamped out. It is inconceivable that there should be in this great republic, in this day and generation, such an economic condition as would allow the mothers of the future race to dwell in squalor, filth, and generally bad and unhygienic surroundings and without sufficient food.

No generation, either of man or animals or plants, determines or provides the future of the race; as a small percentage, as a rule of any species reach maturity and only about one-tenth of those give birth to the next generation. The world may owe much to some of its geniuses whose extraordinary mental abilities may have been, as pointed out by Lombrosa, the expression of epileptic equivalents, or the "degeneration of genius," without the force of which we may not have had the influences of some of our greatest reformers, like Mohammed, Joan of Arc, and others. "A Kant or a Spencer dying childless may leave what we call immortal works, but unless they and their class become parents or unless the average parents of *each* generation are rightly chosen or selected, a new and inferior generation will arise, to whom the greatest achievements of past generations are as nothing—'as pearls before swine.'" The average wholesome people, after all, as Saleeby says, make history that is most worth while.

Some of the great laws—the "Law of Averages" and the "Laws of Evolution"—to which reference has been made, have enabled us to preserve what sanity and stability we have. But for the workings of these laws, we would probably be overrun by the monkey geniuses and the matooids of Lombrosa and other degenerates, as well as thousands of educated, over-cultured inspired idiots and fools of all ages, all or most of whom are capable of propagating their species. Another law applicable, is that nature seems to strive for mediocrity; as a seeming contradiction to this law there frequently arises from the happy mating of so-called common or mediocre folk some splendid children, like the illustrious Abraham Lincoln and many others of the world's notables, who sprang from average, rugged, hard-headed ancestors, who, like Lincoln's immediate ancestors, had a good lineage generations back and an immediate ancestry that was hardy and healthy in the sense that their transmitted characteristics were convergent or cumulative in the person of Lincoln. The same may be said of the famous John and John Quincy Adams, father and son! It is interesting to note in this connection on the authority of Reibmayr, that genius does not carry down the stock and that on the contrary, it is a remarkable fact that the male line, where there are children, rarely extends beyond the third generation (see a list and table of the world's geniuses by Reibmayr). A striking comparison is here suggested between the Adams family of Massachusetts and the notorious Jukes family. The ancestor of the Jukes family, born in Orange County, New York, lived immorally, to a great age and became blind, leaving numerous progeny, many illegitimate. The number of individuals of this family, through several generations, aggregated about 1,200 including mostly criminals, prostitutes, vagabonds, and paupers, and only a small proportion of honest workers.

The sociological side of eugenics was, as far as we know, first emphasized during early Greek civilization. As expressing this Plato, stating clearly the essential idea of inheritance of individual qualities and the danger to the State of a large and increasing number of degenerates and defectives, called upon the legislators and sociologists to purify the State with the result that exists in our own day, namely, that the able-bodied and able-minded continued to be sacrificed to the god of war, while the less fit, the weak, the degenerates and defectives were left at home to become the fathers of future generations. Greece is today and has been for many decades past, a most conspicuous warning of such a policy.

The eugenics of the gigantic world war, involving as it does, most of the great races of men, is racially, economically, and sociologically one of the largest questions connected with the war, or rather of its dreadful consequences. With the flower of the manhood of the belligerent nations engaged in destructive fighting at the front, the normal birth rate in even so fruitful a country as Germany has sharply declined, after the first year of the war, at least 30 per cent. This is true both because of the absence of so many fruitful younger men and because of the impaired physical condition resulting from the stress and privations of war of the men and women who remain at home.

It was observed in France commencing with the first generation after the conclusion of the Franco-German war that the average height of the men was two or more inches less than previous to the war, and this same effect (and other effects of physical stunting) of other great wars have been noted. It is easy to see the effects of children begotten under the conditions named, and under conditions of lowered vitality of the older men who stay at home. Fortunately the law of the continuity of the germ plasm applies in the cases of the thousands of legless and armless fathers, so that their children will not inherit such conditions.

Aside from vicious environmental conditions, we know that tainted heredity from all causes is responsible for the direct inheritance of, and the diathesis to, such mental and neuropathic diseases as the manic-depressive psychosis, dementia precox, epilepsy, imbecility, idiocy, feeble-mindedness, Huntington's chorea, Friedreich's disease (hereditary ataxia), Thompson's disease, familial tremors, muscular atrophies and dystrophies, multiple sclerosis, cerebral hemorrhage, arteriosclerosis, the neuropathic constitution, etc., as well as the diathesis to tuberculosis, diseases of the respiratory mucous membranes, syphilitic taints, heart diseases, eye defects, rheumatism, kidney diseases, skin diseases, etc., as well as cases of alcoholism that are apparently inherited and which must be included in this large class of inherited mental diseases, as must also a certain class of explosive persons who find it impossible to control their impulses and animal instincts.

Some able investigators and thinkers along these lines have concluded that while race impairment is appalling and preventable, the time has not yet arrived, in their opinion, to take genuine, practical steps to remedy the evil. The day and time in which we live is characterized by the stern disposition to meet emergencies and social evils, as never

before, and while I do not advocate too drastic or unconstitutional methods and laws to control the propagation of the grossly unfit, such as confirmed, habitual criminals, rapists, certain defectives, degenerates and feeble-minded, I am of the opinion that the worst of these classes, who cannot be effectively and constantly segregated, should come within the laws enacted by the states of California, Iowa, Indiana, Connecticut, and other States, requiring the sterilization of both men and women of these classes under conditions that safeguard their personal and constitutional rights. That these laws, drastic as they may seem, are not considered inhuman or cruel by those to whom they apply, is evidenced by the fact that individuals not coming strictly within the provisions of these laws have, as is recorded in the State of Iowa, requested that they be sterilized by the operation in the male of vasectomy or, in the case of the female, by the removal and tying off of a small portion of the Fallopian tubes. One of the most urgent reforms in the direction of segregation are better regulations by the Local and State Boards of Health for following up those suffering with chronic alcoholism and also that large class, primary secondary, and some of the tertiary stages of syphilis and other communicable venereal and other diseases; in the case of the syphilitic the observation and regulation should extend for at least a period of five years, after which period they may, in some cases, according to certain authorities, beget healthy children. This suggests every possible extension of the work of the American Association for Education in Sex Hygiene.

Recent laws enacted in the states of New York, Minnesota, and other states of the Union, designed to promote eugenic marriages, require that applicants for marriage licenses shall make a sworn affidavit that they are not suffering with communicable venereal diseases. While these laws may not deter the most thoughtless and vicious, they will undoubtedly prove beneficial by punishing violators, in certain cases, for perjury, and will thus also become educational.

These and other laws and marriage regulations, like those suggested by Dr. Adolf Meyer in his valuable contribution to eugenics and heredity, "The Right to Marry," in which he advocates the publishing in this country for three weeks of the marriage banns, as is widely done in most European countries, will in the end have a salutary effect, both by preventing some ill-considered matings and in a larger degree by calling public attention to this whole subject.

I would suggest that supplementing the marriage laws and regulations already in force in some of the States that there be enacted in every State of the Union uniform laws providing for an impartial board of competent, high-minded physicians and sociologists, to be appointed, as free from political considerations as possible, by the governor of each State, which board shall act upon every application for marriage licenses, with the power, if in their opinion it is necessary, to make a thorough physical and mental examination of every applicant for marriage license. The members of this official board should not in any case receive money or compensation from the applicants themselves, but

should be paid a fixed ample salary by the State, the same fee whether they grant or withhold licenses.

To deal with all of the cases of normal recessives wisely and humanely would constitute a difficult task of the board I have proposed and to deal with even measurable success with this large and important class—in so many cases a useful and helpful factor in society—would solve one of the greatest sociological, economical, and humanitarian problems of the age. Here there is the widest field for the exercise of humanitarianism, good sense, and profound sociological and scientific medical training. The official acts of the board in the cases of most normal recessives should, of course, be in an advisory capacity to those who apply for guidance and advice with regard to mating. Tactful procedure and proper educational methods with them will doubtless bring to them and to society at large astonishing results in a few generations. It is obvious that the membership of the proposed board should be made up of several of the larger elements of society, namely, a physician practically trained in insanity, hereditary diseases, eugenics, criminology, and sociology; two or more members who should represent the dominant religious organizations of the respective States; one member representing the masses of people; a broad minded representative of the best labor and agricultural organizations; a layman who should be a broad student of sociology in the modern sense, and a legal member to safeguard the board in proceeding according to the strict forms of law and the constitution of the respective States and the United States, all of which guarantees the protection of personal liberties of persons to be passed upon by the board. The board should carefully study and, as a whole board, decide the case of each person whose case shall under statute come before the board for vasectomy, ovariectomy, or segregation or as grossly unfit to beget children. This board should be composed of the most highly trained, conscientious, and fearless citizens—men and women—and should be selected and continued in office without political considerations and hamperings. The board should also encourage by an organized campaign of education all who have communicable diseases or known taints or predisposition to insanity, neuropathic states, and other hereditary diseases to freely consult its members or their representatives with regard to the proposed matings of normal recessives and all others proposing marriage. The board's powers should be exercised with prudence and fairness, but it should, nevertheless, be fully exercised to prevent the marriage of the grossly unfit, already mentioned, as well as numerous insane and neuropathic persons, epileptics, and others with certain hereditary diseases.

The details and machinery for the creation and workings of such a proposed board could be made an extension of the present powers of the existing boards of health, local, State, and Federal.

Since the individual is only the product of what is in his father and mother, plus the individual's environment, mating is a matter of vital importance, and it is in this matter that we as physicians can, by employing the laws of eugenics, be of the

greatest service to posterity and to those who are wise enough to consult us regarding proper mating. By encouraging this practice the physician can, more than any other social agent, help to eliminate the inheritance of mental and other hereditary diseases and of bad traits and tendencies.

In spite of our best efforts in the direction of better mating we shall for a long time have defectives in our midst. Believing that many a just cause, scientific as well as moral, has been injured by wild, impractical claims of too enthusiastic but well-meaning reformers, who would in a moment reform everything in the world except themselves, I do not wish to be construed as approaching this subject in the spirit of claiming that eugenics has advanced as rapidly as some other sciences or that it or any of the other of the many sciences have as yet been perfected into exact sciences, or that the beneficial principles of eugenics will or can be so rapidly carried out as to produce in a few decades a perfect race of super-men or super-women, or physical or mental giants, but I do insist that if its great underlying laws are sufficiently understood and seriously considered, that fair-minded men and women will admit that the present investigations and known truths regarding eugenics justify the full acceptance of certain generalities on this subject, which if properly applied would lead to the immense improvement of the race by better breeding and the elimination of a vast number of preventable mental and other diseases.

RIVER CREST SANITARIUM.

Medicolegal Notes.

Action for Malpractice—Contributory Negligence—Expert Evidence—Hypothetical Questions.—In an action for malpractice in setting a broken arm it appeared that the plaintiff broke both bones of his right forearm while cranking an automobile. The radius was fractured transversely at a point about three inches, and the ulna obliquely at a point about five inches above the wrist joint. The defendant was called to set the arm. He first attempted to reduce the fractures with the assistance of a trained nurse, retaining the bones in temporary wooden splints. On the same day he took the plaintiff to a neighboring town, where an x-ray examination disclosed that one of the bones had slipped out of alignment. Five unsuccessful attempts were made by the defendant with the assistance of two other surgeons to reduce the fracture by manipulation. The radius would slip out of alignment at one time and the ulna at another. The three surgeons decided it was a case for incise operation, as, in their opinion, fascia or muscular tissue had intervened between the broken ends of the bones. The plaintiff was thereupon taken to a hospital, placed under an anesthetic, and the fracture treated according to the Lane plate method, three-holed plates being employed on each bone. Because of the danger of splitting the ulna, instead of using the screw in the middle hole, a wire was wound around the plate and bone. The plaintiff continued in the hospital the whole of the next day, during which he developed a considerable temperature and considerable bronchitis. On the following day he insisted on returning to his home, where he suffered a chill, followed by high temperature. The day after reaching home a severe case of infection developed, and the wound over the ulna was on the following day opened and discharged much pus. The plaintiff charged that the infection was due to the use of unsterilized wire or some other negligence in the operation, while the defendant claimed that it was due to a constitutional condition resulting from the bronchial trouble. The wound was dressed twice a day for about two weeks and then

once a day for a few days, when the plate and wire were removed from the ulna. During all this time the wound had been discharging pus, but after the removal of the plate and wire the discharge gradually subsided and finally ceased. The surgeons who had been consulted when the plates were applied, as well as the defendant, subsequently advised a curettement of the ulna for the removal of dead bone and waste matter so as to allow the ends of the living bone to bridge over the fracture. The plaintiff did not consent to the operation until about a month later. There was, however, some evidence that the defendant consented to a delay. At the time of the curettement the bones were in apposition and alignment, and there was a partial union of both fractures, that of the ulna, however, only at one edge, and very slight. On applying the last dressing in September, 1913, the defendant told the plaintiff that there was a delayed union, but with prudent care he would have a good arm by next spring. There was evidence that as early as July, 1913, the plaintiff made some use of his arm in driving his automobile and in working about his store. The fracture did not heal properly, and in August, 1914, the plaintiff had an examination made by another physician and was informed that the ulna had no bony union, but was connected only by fibrous tissue, and that another operation in the nature of bone grafting would be necessary. Later other eminent surgeons were consulted and confirmed that diagnosis. The radius had not healed in proper alignment, but was slightly bowed or curved, and the fractured ends of the ulna were separated by a space of about one-eighth of an inch. In May, 1915, the plaintiff commenced action for malpractice, also alleging fraud in concealing from the plaintiff, at the time the defendant discontinued treatment, that there was a false union, and then assuring him that there was merely a delayed union, which would become complete and perfect in half a year without the necessity of further surgical assistance. The answer denied negligence and also set up contributory negligence in leaving the hospital contrary to instructions, in prematurely using the arm, and in failing to comply promptly with the defendant's recommendation to submit to a curettement. The plaintiff obtained a verdict and judgment in the trial court. The judgment was reversed on appeal by the Washington Supreme Court, which made the following rulings:

A charge against a physician of negligence in the choice of a treatment is refuted as a matter of law by showing that a respectable minority of expert physicians approved of the method selected. Where a physician is charged with negligence in the actual performance of a treatment after its method was chosen over others; if there is any evidence tending to show such negligence, the case is for the jury, though the method of treatment itself is one approved by a respectable minority of physicians. The questions of the defendant's negligence and the plaintiff's contributory negligence were both held for the jury. It was held that the opinion of a medical expert, in an action for malpractice, is admissible, though based on the study of books rather than his own experience, so that an osteopathic physician was not disqualified as a witness in an action for malpractice against an allopathic physician because he had no right to practice the allopathic system and had only a theoretical knowledge of it.

Hypothetical questions to a medical expert testifying in an action for malpractice calling for the witness' opinion as to whether or not the use of a single screw in each end of the plate used to secure fractured forearm bones accounted for the healing of the radius in a bowed condition should have included a reference to all the conditions, among them the use of external splints and casts. A hypothetical question directed solely to the manner of placing the plates should have included the fact that splints or a cast and wire wrapping were also used. A question relating to the cause of infection of the arm, including an assumption that a wire used to wrap the bones was not sterilized, and the answer thereto, should have been excluded as assuming negligence, while the evidence on the point was conflicting. A hypothetical question directed to the failure to remove certain tissue at a certain time, assuming a fact of which there was no evidence, should have been excluded.—*Swanson v. Hood*, (Wash.), 170 Pac. 135.

Military Medicine.

AVIATORS' SICKNESS.

THE General Direction of Aeronautics, Italy, has instituted at Naples and Turin a psychophysiological research into the proper testing of aviation candidates for organic and functional disqualifications. The movement is under the supervision of Gradenigo and Herlitzka. In the end the rarefaction of the air will, of course, unless compensated, prove too great a barrier for the most perfect human machine and the hardest pilot must suffer. What then may be done for the inevitable ailments? In the March 31 number of the *Giornale di medicina militare*, Aggazzotti of the Physiological Department of the University of Turin considers the subject of the treatment of rarefied-air sickness, a malady which must be overcome if the Italian aviators are to maintain superiority. The writer has recently interviewed Captain Ruffo, who has won many battles at high altitudes. This expert informed him that at 6,000 meters (about 20,000 feet) there is experienced a heaviness of the head, a somnolence and mental and physical torpor which is very prejudicial to the chances of the fighter in an air combat where all depends on quickness of wit and movement. The syndrome is one of nervous depression due purely to rarefaction of air, such as can be studied in pneumatic cabinets on man and the higher animals. In such a cabinet the author has experienced the same sensations when the air pressure was reduced to 360 mm. mercury, equal to an altitude of 6,000 meters. This degree of rarefaction represents the limit of human adaptation. To proceed further would surely mean complete defect of all of the higher faculties. Nevertheless some aviators could sojourn for a brief interval as high as 7,000 meters; while on the other hand the altitude 4,000-7,000 meters is a zone in which all aviators suffer more or less from rarefaction. As is well known, mountain sickness occurs at a lower level—3,000 to 4,000 meters (9,750 to 13,000 feet)—because to the influence of rarefaction of air is added fatigue. The author has seen amateur photographers climb to this elevation, but once it was attained the mountain sickness robbed them of all their esthetic feelings and they became entirely indifferent to the magnificence of the scenery.

The aviator may suffer from symptoms not due to rarefaction. In rapid descent he experiences discomfort from recompression, just as in the pneumatic cabinet. One such symptom is earache from entrance of air into the drum. A little water sipped during recompression may prevent this disorder, for it makes swallowing possible so that the entrance of air into the ear drum is not so abrupt. During ascent the throat becomes dry and swallowing difficult. Another preventive is the holding in the mouth of some article or substance to stimulate the production of saliva.

To return to air rarefaction, its mechanism has been studied exhaustively by Mosso. Two components are in evidence, viz., anoxemia or too little oxygen in the blood and acapnia or too little carbon dioxide. In other words, too little oxygen

enters while too much CO₂ escapes from the blood. The diminution in the weight of the air upon the surface of the body cuts no figure. The use of oxygen reservoirs was tried out many years ago in ballooning. Even when 60 per cent. of oxygen was present in the respired air the men could not ascend above 8,000 meters (26,000 feet) and two men succumbed during the tests. The author has therefore experimented with certain mixtures of air in the pneumatic cabinet in which both O and CO₂ were present in excess—for inhalation of CO₂ is the rational remedy for acapnia. The first mixture used was O 67, CO₂ 12.7 in a rarefaction equal to 6,000 meters altitude. The effects were all that were desired and the author then rarefied to a mercury pressure of 140 mm.—equal to an altitude of more than 13,000 meters. The author made this experiment on himself and inhaled 11 liters of the breathing mixture at the rate of 22 inspirations a minute. He remained in this rarefaction for 18 minutes without disturbance of any sort. He continued with still greater rarefactions—much higher than have ever been reached in balloons—equal to an altitude of more than 50,000 feet—all without any disturbance as long as the O-CO₂ mixture was breathed. Mosso's explanation of altitude sickness as anoxemia plus acapnia seems firmly established.

It has long been known that muscular exertion can neutralize rarefaction to a certain extent for the obvious reason that more O is consumed and more CO₂ formed—just as if a certain amount of the breathing mixture had been breathed. As a result of what we now know aviators will be provided with tanks of the O-CO₂ mixture containing 300 liters. They are not to breathe the mixture exclusively but from time to time as needed. It will probably be found best to compress the mixture into small containers. Special masks will be necessary as in differential overpressure work in thoracic surgery.

Odd Death of a Malingerer.—Suicide in soldiers is by no means unknown, while malingering to escape duty is only too common; but it is doubtless extremely rare for an ordinary malingerer to cause his own death by inadvertence. Professor Pusateri reports such a sequence in the *Archivio italiano di otologia* for February 28. A soldier who had a strong motive for getting home took the chance that a burn behind the right ear made with nitric acid would lead to his being invalided temporarily, or discharged. He was at once seized with high fever, vomiting, vertigo, and acute pain in the mastoid process. Seventeen days later he presented right facial paralysis and one week after profuse and then persistent hemorrhage from the ear and nose. The latter ceased spontaneously within a month. Five months after date of injury, a slight otorrhea having persisted, he underwent exenteration of the tympanum without benefit. He was now allowed to go home, after which some of the various symptoms reappeared—fever, profuse nosebleed, etc.—and death occurred with patient unconscious six and one-half months after receipt of the lesion.

Autopsy revealed the mechanism of the case.

Aneurysms had formed in both the bulb of the internal jugular vein and the internal carotid artery, and these had undergone rupture. Erosions had previously been caused by the aneurysms in the vault of the carotid canal and inner aspect of the dura and pus had formed in the middle fossa of the skull, so that a large abscess cavity resulted with fusion of the carotid canal and jugular fossa, and implication of the tympanum. The immediate cause of death had been leptomeningitis. The necrotic and suppurative process initiated by the nitric acid burn had implicated the walls of the two large vessels. The medical history of the war shows that injury to the ear is rather a favorite mode of malingering because not so readily suspected as other self-inflicted lesions, or perhaps because lesions affecting the ear are more apt to procure the desired furlough or discharge from military service.

Deliberate Bombing of Hospitals Continues.—With the renewal of the German offensive come reports of several air raids on hospitals. Among these was an attack on a Canadian Hospital, which exacted a considerable toll of casualties. Among those killed was an American medical officer who was administering an anesthetic to a British officer in the operating room. This hospital was a large one marked by huge Red Cross signs. Several apparently deliberate attempts have also been made to destroy American hospitals behind the lines in Picardy. Bombs were dropped on one hospital in which there were scores of American wounded and hundreds of French sick and wounded. It is said that nearly every window in one hospital was shattered and that it was necessary to remove the patients to the cellar. As the wounded continued to be brought to the hospital the surgeons worked on through the night in the midst of the attack. Among the men who stuck to their work were Major Fred G. Murphy of St. Louis, Captain Charles Farmer of Louisville, Ky.; Lieutenant Joseph McDevitt of New York City, Lieutenant Thomas Hardy of Richmond, Va., and Dr. William Clark of Washington, D. C. Andrew Bonar Law, the government leader in the House of Commons some time ago, told the lower house of parliament that 300 casualties to hospital cases had been caused by the bombing of British hospitals in France by German aviators. Since then a number of other hospitals have been attacked by the German miscreants.

United States Preparing Hospitals in London.—The United States Army took over a 2,000-bed hospital in London on May 29, for the care of American wounded. The hospital is to be operated by an American medical staff consisting of 50 doctors, 150 nurses, and 300 orderlies. Plans have been completed for the erection of an American hospital in Windsor Park for the care of wounded Americans. It will be composed of huts and will be equipped with 500 beds.

American Doctors Captured.—A German telegram to Amsterdam, giving an account of the fighting along the Chemin des Dames, mentions that among the prisoners taken from the British were a number of American doctors.

Health of Army Camps.—A report from Washington, under date of May 30, states that health conditions throughout the home camps continue good. The report of the surgeon-general for the week ended May 24 shows that pneumonia is prevalent at Camp Travis, Texas; Camp Dodge, Iowa, and Camp Gordon, Georgia. Measles continues to be prevalent at all the camps. Deaths for this week numbered 161 as against 178 for the preceding week.

Narcotic Inquiry in Camps.—Dr. Charles A. Rosenwater of Newark, N. J., recently submitted to Secretary Baker a survey which he made of the Southern States for the Alabama and Georgia Boards of Health with reference to the use narcotic and habit forming drugs. The report states that the Harrison law is inadequate to cope with the illegitimate traffic in habit-forming drugs and cites a purchase of 200 ounces of cocaine for export which it is believed ultimately reached American soldiers. Dr. Rosenwater urges a thorough investigation of the army camps in reference to the use of narcotic drugs.

Medical and Divinity Students Must Register.—The War Department authorizes the following statement from the Provost Marshal General: "Divinity students and students of medicine must register. Registration comes first and exemption afterwards. It is absolutely necessary that these students register." The only men not affected by the new law are those now actually in the military or naval service.

New York Hospitals Aid Draft Registrants.—The hospitals of New York City have notified Adjutant General Charles H. Sherrill that they are prepared to give surgical and medical treatment to those registrants of Class I who have been classified as eligible for military service subject to necessary surgical operation or medical treatment. This action was taken in response to an appeal from the Government. Dr. Victor C. Pederesen, chief medical officer of the selective draft for New York, will be in general charge of this part of the draft work in New York.

First Prosecution for Food Hoarding.—The first prosecution for food hoarding under the terms of the food control law was undertaken on May 29 by the Food Administrator of the District of Columbia. The indictment handed up by the Grand Jury in the Supreme Court of the District of Columbia charges a naval surgeon and his wife with the hoarding of nearly \$2,000 worth of food stuffs, a quantity far in excess of the needs of their family.

Red Cross Drive for Nurses.—The Atlantic Division of the American Red Cross started a drive for nurses on June 3. It states that 5,000 additional nurses are needed by the army right now. Ten thousand should be available by January 1, 1919. The expansion of the American Army abroad may demand the enrolment of 25,000 additional nurses before the close of the year. The campaign will be carried on by moving pictures, meetings, and speeches. Hospitals and schools will be enlisted in the effort to get more young women to enroll as pupil nurses.

Petition President to Retain Surgeon General Gorgas.—The American Laryngological Associa-

tion, the Laryngological, Rhinological, and Otological Society, and the American Otological Society, which held their annual meetings in Atlantic City during the week of May 27, drew up petitions which will be submitted to President Wilson requesting that General Gorgas be continued in his present office as long as he is physically able to perform his duties. General Gorgas will attain the age limit which would place him on the retired list after October 1, 1918. The resolutions formulated express the opinion that it would be a national misfortune to lose his services at this time.

Mackay Home Offered As Hospital.—Clarence H. Mackay has offered his estate at Roslyn, L. I., with its 600 acres of land and buildings, to the American Red Cross for use as a base hospital. It is estimated that four or five hundred patients could be cared for without difficulty.

Medical Aid for Palestine.—The New York Chapter of Hadassah, the women's Zionist organization, announces that it has about completed the organization of a medical unit for Palestine. The equipment still lacks a motor truck and an appeal has been made for \$1,000 to provide for this need. This unit, consisting of fifty-one physicians and nurses, will form the foundation of a large and permanent system of medical relief work that is to be conducted on a basis of assistance to all who need it, irrespective of race or religion.

American Doctors Honored.—Captain Thomas Edward Walker and Lieutenant Linwood M. Gable of New York have been awarded the British Military Cross. Other American lieutenants in the Medical Service similarly honored are Arthur Irving Haskell, James B. Clinton, Samuel Adams, Gouverneur Boyer, Harold Foster, John Gregg, Albert I. L. Jones, Baldwin L. Keyes, Guy D. Tibbetts, and Harvey C. Updegrove.

Woman Doctor In Army.—Dr. Loy McAfee of New York has been appointed to the Army Medical Department in Washington, with the official title of contract surgeon. Her duties are those of secretary to the Board of Publication of the Surgeon General's Office.

Mayor Hylan Discourages Enlistment.—Dr. Curtin, an assistant medical examiner in New York City who was recently commissioned captain in the Medical Reserve Corps of the U. S. Army, applied for leave without pay during his term of army service. The mayor refused to grant the leave, thus forcing Dr. Curtin to resign from the service of his country or to give up his appointment as assistant examiner. Of course he remained in the service of his country.

A Million Invalid Prisoners.—A recent communication from Moscow to the Associated Press states that of 3,100,000 Russian war prisoners held in Germany and Austria-Hungary 1,000,000 are total invalids. It is said that one-half of these prisoners are in the last stages of tuberculosis and that the rest are suffering from other contagious diseases. Their return to Russia presents a great problem on account of lack of food, proper accommodations, and medical assistance.

War Medals for American Doctors.—It is reported from France that more than thirty American doctors have been recommended for the American

Distinguished Service Medal in recognition of great bravery. During a recent shelling and gas attack, in which many American troops were wounded or gassed, the medical corps men rushed to the scene of the attack and in the midst of the shells and gas removed their masks in order to work rapidly and give relief to as many of the wounded as possible before they themselves fell victims of mustard gas. Some of these men have also been recommended for the French War Cross. The army regulations forbid the mention of the names of these heroes until the recommendations for the granting of the medals have been approved.

Many Disabled Germans Returned to Ranks.—According to a report recently made to the Reichstag by Surgeon General Schultze more than 2,700,000 wounded and sick men have been returned to the fighting front, and 692,000 soldiers have been discharged from the German Army as unfit for further service. Surgeon General Schultze declares that the percentage of men discharged from the hospitals as fit for further service is very high, but the number of cripples at this time is about 98,000. With the exception of those killed the deaths in the army were from 1 to 1½ per cent. of the wounded.

Senators Oppose Rehabilitation Under the Education Board.—The bill proposed by Senator Smith of Georgia which provides for placing the work of the rehabilitation of disabled soldiers with the Federal Education Board and carries an appropriation of \$2,000,000 is meeting with considerable opposition. The opponents of the measure claim that obviously the War and Navy Departments, each through its Surgeon General's office, form the natural and most effective agency in which authority should be concentrated, but they believe that the Board of Education and the Federal Board for Vocational Education should be represented. A central and unified control for administering the rehabilitation work was urged in resolutions adopted by the National Education Association's Commission on the National Emergency in Education.

American Hospital Near Front Lines.—A report from the American Army in France to the Associated Press describes some of the work of the American Hospital units near the front. They have won high praise by the establishment of a non-transportable field hospital only a short distance from the front line, the first of its kind to be introduced. With this hospital and equipment it has been possible to perform operations that hitherto have been impractical at the front, and they have thereby been able to save the lives of many more soldiers than could otherwise have been done. Of 155 cases recently admitted, operations were performed on 118 men and the mortality was only 30 per cent., whereas under the former methods a mortality of 80 to 90 per cent. would have been expected.

United States to Start School of Nursing.—Secretary Baker has authorized Surgeon General Gorgas to establish an army school of nursing to train women for service in the military hospitals. The location of the school has not yet been selected. Branch schools will be located in various military hospitals.

ACUTE INFECTIOUS JAUNDICE.

ACUTE infectious jaundice has been more or less prevalent among the allied armies almost from the outset of the war. The disease is one that presents many features of interest to sanitarians of this country, mainly on account of the fact that it is presumably conveyed by the agency of the rat. It is believed that in the great majority of cases this type of jaundice is due to the *Spirocheta icterohemorrhagiae* discovered by Inada and his coworkers. In *Public Health Reports* for May 10, 1918, is a paper by Dr. M. H. Neill, Passed Assistant Surgeon, U.S.P.H.S., dealing with the problem of acute infectious jaundice in the United States. He points out that Noguchi found that rats captured in New York City and neighborhood were infested with a spirochete identical in appearance with that causing acute spirochetal jaundice in man. Neill, by means of cross immunity tests, obtained further evidence that the parasites causing the human disease in Europe and Japan and those found in New York rats were the same. All evidence, indeed, seems to indicate pretty conclusively that *Spirocheta icterohemorrhagiae*, the cause of acute spirochetal jaundice in man, is rather widely disseminated among rats. Epidemic jaundice was prevalent during the Civil War, according to reports, and epidemics of jaundice simulating closely those known to be caused by *Spirocheta icterohemorrhagiae* have occasionally appeared in this country, and were possibly due to this parasite.

English and French workers have demonstrated the presence of *Spirocheta icterohemorrhagiae* in rats taken from the trenches in which the disease prevailed among troops. Neill draws attention to the fact that with regard to the relation between rat infestation and human infection with this spirochete, two possibilities present themselves. First, it is possible that no transfer from rats to man takes place, or only exceptionally, as in case of a bite. It may be that some cause is at work in the trenches and mines which tends to infect man and rats with the spirochete entirely independently of each other. On the other hand, it seems more probable that the spirochetes may be interchanged between men and rats living in such environments as obtain in the trenches, by means of their urine.

There is evidence to show that infection can take place either through the skin or by the mouth. There is no adequate evidence that any insect plays a part in the transmission of the disease in nature, although the experimental evidence in this regard is by no means complete. The epidemiology of the disease appears to point rather definitely to a moist soil at an equable temperature, as a means of keeping alive the virus.

Neill thinks that from a consideration of all the points involved, the following is a reasonable hypothesis of the mode of transfer. About 10 per cent. of all wild rats, wherever located, probably carry the *Spirocheta icterohemorrhagiae* in their kidneys and excrete them in their urine. If this organism finds a favorable environment in the soil a sufficient number may live long enough to infect a human being, who gets them in the mouth or on the skin. Under these conditions a larger number of rats also take up the spirochetes.

The evidence that acute infectious jaundice is caused by a spirochete is fairly clear, and that the rat is a carrier of the disease appears to have been proved. The manner of its transfer to man is somewhat obscure, but Neill's hypothesis appears as reasonable as any which has been advanced. In view of the fact that the rat conveys the disease, the logical mode of prevention, or at least of arresting its spread, would seem to be the destruction of rats. Unfortunately, the rat is an animal particularly difficult to eradicate, and a campaign against him must be characterized by a cunning equal to his own. The deratization of cities visited by the plague has been effected, and although the conditions in the trenches are less favorable the freeing of them from rats does not seem impossible of accomplishment.

THE VITAMINE CONTENT OF CEREAL FOODS.

THE question of food is the dominant factor in the present situation. Of all foods, bread is the most important, that is among Europeans, and the inhabitants of this Continent. The reputation of bread as a nourishing article of diet has been considerably enhanced during the present war. Indeed, the staple of diet among the Italians, French, and Austrians is bread.

This being so, the object is to present bread in its most nutritive form. The bulk of the cereal component of the diet of people of Europe is represented by wheat bread. Now all natural cereals contain an abundance of antineuritic vitamine, an accessory food element the consumption of which in sufficient quantities is essential to good health. Moreover, it is believed, in fact seems to have been proved, that the vitamine content of a cereal is in the outer covering of the grain. But flour made by modern milling contains, as a rule, only about 70 per cent. of the wheat from which it is milled. Therefore, the important question remains, does bread made from "white" flour or "highly

milled" corn meal include all the essential food elements contained in the intact grain.

In Public Health Reports of May 3, 1918, Carl Voegtlin, G. C. Lake, and C. N. Myers have a paper which continues the work done by others with respect to the antineuritic vitamine of corn and wheat products used in nutrition. Pigeons were employed in their experiments and full-grown birds were used. Their conclusions were as follows: (1) The results obtained in the investigation clearly show that for pigeons an exclusive diet of whole wheat or corn furnishes an adequate supply of antineuritic vitamine. (2) The antineuritic vitamine seems to reside in the peripheral layer, whereas the endosperm is relatively poor in the substance. (3) If wheat and corn foods containing only a small percentage of the peripheral layers and germ of the seed are fed to pigeons and chickens exclusive of other food, polyneuritic symptoms appear on an average of three weeks after the beginning of the feeding period. The appearance of polyneuritis is preceded by a gradual loss in body weight. The birds can be relieved of their paralysis in a striking way by the oral or subcutaneous administration of a highly concentrated preparation of antineuritic vitamine derived from "whole wheat" bread, yeast, ox liver, rice polishings, or beans. (4) The addition of yeast, in amounts used by bakers in the preparation of bread from highly milled flour, does not prevent the appearance of polyneuritis in birds fed on this food, but prolongs slightly the period of incubation. (5) The addition to highly milled flour or to bread made from highly milled flour of a small amount of antineuritic vitamine preparation will correct this particular dietary deficiency, and will prevent the appearance of polyneuritis and the loss of body weight. (6) The total phosphorus content of corn and wheat foods is a fairly satisfactory index of the amount of antineuritic vitamine contained in these foods. In a general way, it can be said that a high total phosphorus content is an indication that the particular corn or wheat product is relatively rich in antineuritic vitamine.

These investigations further clinch the argument that whole wheat and corn breads are the most wholesome. The authors in a subsequent paper will consider certain other dietary attributes of these foods in their relation to growth.

THE EQUILIBRIUM REACTIONS IN TESTING THE FUNCTIONS OF THE INTERNAL EAR.

THE Bárány tests have been much used of late in connection with fitness for aviation and also after injury involving the labyrinth. Irrespective of war conditions there is also an extensive field for these tests in the diagnosis of the nature of vertigo. Coulon, in a contribution to the *Revue de laryngologie, otologie et rhinologie* for April 15, expresses the opinion that this species of testing is imperfectly carried out. He mentions first the caloric tests with cold water—18° to 25° C.—and warm

water—40° to 45° C. These he has used over a hundred times with the following results: In the normal subject cold water gives a lateropulsion toward the irrigated side while with warm water this behavior is reversed. With cold water after 30 to 40 seconds of irrigation nystagmus appears, usually rotatory but sometimes horizontal, on the opposite side and of one minute's duration. With warm water the latent interval is 60 to 90 seconds, the nystagmus appears on the irrigated side, and the duration is 1½ to 2 minutes. In subjects with labyrinthine disease the latent interval and duration both vary, according as we have to deal with hyper- or hypoeccitability or nonexcitability.

In the rotation test the subject closes his eyes or has them bandaged and is turned in his chair evenly 10 times in 20 seconds. Instead of the confusing words right and left, Coulon prefers positive and negative; but as the result is quite the same irrespective of direction the distinction is not vital. The nystagmus produced is rhythmic and indicates that the vestibule reacts. Positive rotation gives a left nystagmus and left lateropulsion, and negative rotation the reverse behavior. The author modifies the rotation as follows: The shoulders are fastened to the chair while the head is held in the operator's hands as rotation is practised 40 times in 30 seconds. At the moment of cessation both nystagmus and lateropulsion usually appear in the normal subject. In the positive test right nystagmus appears and lasts 15 seconds and in the negative test left nystagmus of about the same duration. In disease of the vestibule we also see the reactions of hyper-, hypo-, and nonexcitability. These tests should be used in all cases of shell shock, etc., in order to learn whether or not the internal ear is compromised. The symptomatology in these cases is barren enough and any induced tests which can throw light on the underlying pathology should be welcome.

THE IMPORTANCE OF ELIMINATING THE POTENTIAL NEUROTIC.

If the present war has demonstrated one thing forcibly, it is that physical excellence is not necessarily synonymous with the highest efficiency as determined by the actual accomplishment of hazardous tasks. This does not mean that physical perfection and freedom from bodily disease are factors to be ignored in the slightest degree, but rather that the mental and psychic features of the prospective soldier should also be scrutinized with the idea of determining his ability, in so far as it is possible, to stand up under the terrific strain that he will eventually encounter when he gets into active service. The old adage, "mens sana in corpore sano," is particularly apropos at this period in the history of the world. It is now a matter of record, however, that deeds of courage and bravery have been performed in this great conflict by men who could not be classified as physically robust, but who possessed well-balanced minds that were able to resist the

repeated psychic shocks to which they were exposed.

The problem of how to detect the mental stability of recruits without consuming too much time in detailed psychological tests, has not as yet been thoroughly worked out. Progress is being made in this direction and valuable data are being accumulated constantly. Morgan, in discussing the situation in *The Scientific Monthly*, January, 1918, calls attention to the fact that intelligence tests, as usually applied, will not detect the potential neurotic, who may break down under long-continued strain. Undoubtedly the number of such individuals is fairly large. Morgan is of the opinion that if no test can be used now with enough confidence to make a selection of recruits, tests that look promising could be made on all those examined, the records of those who succumb being compared with the records of those who survive the strain. He points to the fact that this procedure would give information which would be valuable not only in war time but also for use in vocational guidance in times of peace. It is quite evident that the problem is decidedly worth while following up, not only by way of averting loss to the government, but for the good of the recruit himself. That the Army Medical Department is fully alive to the importance of this phase of the examination is indicated by the appointment of several expert psychologists and psychiatrists to the service.

THE PREVENTION OF VENEREAL DISEASE.

IN this country, and more especially in Europe, there has been free and somewhat acidulated discussion as to the best methods of preventing venereal disease. There is no doubt with regard to the prevalence of both syphilis and gonorrhea, and there is also no doubt that these diseases constitute a serious menace to the public health. All this is recognized by the medical profession at large, but its individual members are at odds regarding the most efficient means of staying the plague. It has been stated on excellent authority that direct prophylaxis on the Metchnikoff plan, if used in time, is a sure preventive, and the records of practical experience appear to bear out the statement. An attempt has been made recently by a portion of the medical profession, to introduce direct prophylaxis into Great Britain or, at any rate, into the army. However, the attempt has met with much opposition based on so-called moral grounds. A controversy is raging at the present time in the medical and lay press between champions of personal prophylaxis and those who hold contrary views. The opponents of the method, while allowing that it may be and probably is all that is claimed for it as a prophylactic, take the stand that it is quite arguable that venereal disease may be abolished at too great a moral cost, tragic though the consequences of inaction may be to innocent women and children and the public health generally. The cost referred to is the State recognition and practical encouragement of sexual vice as a necessary evil. On the other hand, the supporters of the method contend that this phase of the question is disposed of by relegating it to instruction by "parents, guardians, priests, dea-

cons, and philosophers," or teachers and governesses. Moreover, the advocates of direct prophylaxis assert that it would not be long ere venereal diseases would be entirely eradicated if such measures were strictly carried out. Dr. Montague Lomax, writing in the *Medical Press*, April 3, 1918, weighs the "fors and againsts" and, although he endeavors to maintain an open mind, it is plain to see that he apprehends many difficulties in the way of making direct prophylaxis general. He does not believe that promiscuous sexual intercourse can ever be physically right. In his opinion "rightness" is a question of morals, and morals alone. An action may be physically natural and yet not physically right. Lomax strenuously contends that chastity, whether voluntary or enforced, does not do a tithe of the harm, personal and social, that results from promiscuous unchastity. While it may be extremely hard from many points of view to reconcile the moral and physical aspects of the case, yet at the same time the fact must be borne in mind that soldiers should be protected, at least during war time, against the contraction of venereal diseases. If direct prophylaxis used in time will prevent infection, then by all means direct prophylaxis should not only be practised among soldiers, but enforced. Good health is essential to the fighters.

News of the Week.

The Primary Causes of Shock.—In the article under this title, by Dr. Turck, published in the MEDICAL RECORD of June 1, the following errata are to be noted: On page 928, 2d column, 6th line from the top, the reference figure ¹⁴ should be ¹⁸, and in the 5th line below this ¹⁷ should also be ¹⁸; on page 929, 1st column, 21st line from the bottom, reference figure ³ should be ³¹. On page 932, the legends of Figs. 3 and 4 should be transposed.

Grippe Epidemic in Madrid.—An epidemic resembling grippe is sweeping over Spain with increasing severity. There are said to be more than 150,000 cases in Madrid. Over 600 doctors are suffering from the effects of the malady, which very much hampers efforts to fight the epidemic.

Epidemic of Dropsy.—Advices recently received from Copenhagen state that an epidemic of dropsy has broken out in Sweden which is attributed to poor and insufficient food. Several thousand cases of the disease are reported.

China Suffers from Epidemic Influenza.—A despatch from Peking reports that a curious epidemic somewhat resembling influenza is sweeping over North China. There are 20,000 cases in Tientsin and thousands in Peking, where business places have been closed down. The affection is not fatal and runs a short course.

Fire in State Hospital.—A fire which destroyed one of the wards of the State Hospital for the Insane at Columbia, S. C., resulted in the death of sixteen patients. Eleven others are missing and five were seriously burned.

German Hospitals Change Their Name.—The Ways and Means Committee of the Board of Trustees of the German Hospital, Brooklyn, has drawn up and presented a petition to change the name of that institution. The petition will be acted on at the next meeting of the Board of Trus-

tees on June 10. It is reported that the German Hospital in Manhattan will also change its title. The institution hitherto known as the German Hospital of Newark has changed its name, under a re-incorporation, to the Newark Memorial Hospital.

British Doctors Arrive.—A delegation from the British Medical Association arrived in this country on May 29, having come to attend the meetings of the American Surgical Association and of the American Medical Association. The delegation included Sir James Mackenzie, Sir Arbuthnot Lane, and Colonel Herbert A. Bruce, consulting surgeon of the British forces in France.

Hospital Heads Resign.—Three heads of departments of the Cumberland Street Hospital, Brooklyn, have sent in their resignations because they disapprove of the plans of Commissioner Coler for reorganization. Commissioner Coler plans to do away with that form of organization under which there is a head for each department and to go back to the old method whereby a general staff is created with the members taking turns in the various services. The men who have resigned are Dr. Herbert C. Allen, Dr. J. Hubley Schall, and Dr. E. Rodney Fiske.

Death of a Centenarian.—Mrs. Aristine Pixley Munn, widow of Dr. Edwin G. Munn and mother of Dr. John P. Munn of New York City, died at her home at Gates, N. Y., on May 29. She was 100 years old on October 29, 1917. She retained good health and a clear mind up to the time of her death.

Accused Health Official Denied Trial.—Dr. Lucius P. Brown, director of the Bureau of Food and Drugs of the New York Health Department, who was suspended pending the investigation of charges made against him, has been formally charged with neglect of duty, inefficiency, and incompetency, and will be granted a hearing on June 10. It was understood that he was to have an open trial with the privilege of calling witnesses and of being represented by his counsel. Such a trial has been denied him for some reason by Health Commissioner Copeland; the public, however, will graciously be permitted to be present at the hearing.

General Gorgas Addresses Medical Faculty.—Surgeon General William C. Gorgas delivered an address before the Faculty of New York University and Bellevue Hospital Medical College on the afternoon of June 5 on "The Activities of the Medical Department of the United States Army." The address was delivered in the auditorium of the Carnegie Laboratory.

Benefit for People's Hospital.—A recent benefit performance at the Maxine Elliot Theater for the new building of the People's Hospital netted \$50,000.

Dr. Charles E. Nammack of New York has removed to No. 379 Park Avenue.

Medical Society Elections.—The AMERICAN PEDIATRIC SOCIETY, at its thirtieth annual meeting in Lenox, Mass., on May 27, 28, and 29, elected the following officers: *President*, Dr. Edwin E. Graham of Philadelphia; *Treasurer*, Dr. Charles Hunter of New York; *Secretary*, Dr. Howard C. Carpenter of Philadelphia; *Treasurer*, Dr. Charles Hunter Dunn of Boston; *Recorder*, Dr. Oscar M. Schloss of New York.

Obituary Notes.—Dr. NEIL JAMIESON HEPBURN died at his home in New York City on May 28, aged 71 years. He was a graduate of the College of Physicians and Surgeons, New York, in 1868, a Fellow of the American College of Surgeons, a member of the American Ophthalmological Society and the American Otological Society, consulting ophthalmologist to the Manhattan Eye, Ear, and Throat Hospital, and the Paterson, N. J., Eye and Ear Infirmary. Dr. Hepburn was a member of the Old Guard. He served in the Sanitary Corps during the Civil War.

Dr. LEWIS E. MEEKER, retired, died at his home in Brooklyn, N. Y., on May 23, aged 67 years. He was a graduate of the Detroit Medical School in 1872. He was formerly president of the Eastern District Savings Bank of Brooklyn.

Dr. STEPHEN W. DRIVER, a graduate of Harvard Medical School, in 1863, and for twenty years secretary of the Harvard Class of 1860, died at his home in Cambridge, Mass., on May 21, aged 85 years.

Dr. W. CONSTANTINE GOODELL died at Philadelphia, on May 14, at the age of 55 years. He was graduated from the medical department of the University of Pennsylvania, in the class of 1885. He was a son of the late Dr. Wm. Goodell.

Dr. NICHOLAS B. VANHOUTON of New York City, a graduate of the College of Physicians and Surgeons, New York, in 1867, and physician and surgeon of the Rockland County Jail for forty years, died on May 29, aged 76 years.

Dr. FRANK OAKLEY STOCKTON, a graduate of the College of Physicians and Surgeons, New York, in 1881, died at his home in East Orange, N. J., on May 27, aged 69 years.

Correspondence.

THE VOLUNTEER MEDICAL SERVICE CORPS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Your editorial on the Volunteer Medical Service Corps must have given real delight to the many "stay-at-home" physicians who for one reason or another are ineligible for the Reserve Corps, and who are, nevertheless, anxious to serve. The formation of the new volunteer corps will give thousands of physicians the opportunity they have been hoping for, namely, that of serving in or near their homes.

It would appear, however, from your editorial explanation of the workings of the volunteer corps that its members will be called upon only from time to time, at such times when there may appear to be some need for the special services which they may be able to render. If this interpretation of the new corps is correct, it appears to the writer that comparatively little, if anything, will be gained by the military medical service at large, for the opportunities thus afforded for actual service will not be very great or numerous.

This volunteer corps can be made a most important factor in the medical service by an intelligent study of its great possibilities. To the writer it has appeared perfectly feasible to utilize the services of the "stay-at-homes" to their fullest capacity, and thus release for duty abroad many young, active

men who are at present doing routine work here which can be done very well, and even better, by the men who are about to constitute the volunteer corps.

It is not unusual to hear of a young surgeon who enlisted in the Reserve Corps, in the hope of active service abroad, being detailed to some receiving or evacuation station, performing duties for which he is not fitted by training or inclination, while the work that he can best do is being done indifferently by some other man equally misplaced. As an example, a man who has been specializing in *x-ray* work for years was detailed as internist in a large Western camp, while other medical men were being instructed as radiographers to make good the shortage.

It is evident that such things had to happen when the sudden expansion of our medical service took place, but it is likewise evident that this state of affairs is largely due to the fact that men who ought to be serving in France in their most efficient capacities were needed at home to take care of the camps, receiving, and evacuation stations. If, however, the system were made so flexible that the "stay-at-homes" could be utilized for the work at the camps and other local stations, hundreds and possibly thousands of regular Reserve Corps men would at once be released for active duty abroad.

This is the suggestion the writer has in mind: That the medical needs of local camps, local base hospitals, and stations be taken care of, as far as possible, by members of the volunteer reserve corps, working in the same non-resident manner as the visiting staff of a hospital. The volunteer reserve corps will include among its members the most competent and expert men in the profession, who, because of age or physical defects or dependents, are unable to go abroad. It would appear to be wise policy to utilize the services of these men, not spasmodically, as special occasion may call for, but continuously, for the duration of the war. Every man can give up some part of his time; some can give up mornings, some afternoons. Between them the full day can be covered, and the medical service would thus be enriched by the valuable experience and abilities of these mature men.

The volunteer corps would be a splendid addition to the regular Reserve Corps, but the men who join it should give up as much time as possible, and should serve continuously and not spasmodically. In this way the shortage of physicians in Europe will be materially relieved.

ABR. L. WOLBARST, M. D.

113 EAST NINETEENTH STREET, NEW YORK.

QUININE AND WARBURG'S TINCTURE IN MALARIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In your issue of May 18 there is an article by Dr. Beverley Robinson on the treatment of malaria, in which he strongly advocates the use of Warburg's tincture in malaria instead of quinine, and of which he expects the "happiest results." In some forms, he says, nothing remedial equals or approaches the value of this tincture, and he can recall not a few instances where quinine failed him and the Warburg tincture, fortunately, helped cure the patient.

I would not try to minimize the therapeutic value of the tincture, but it seems to have escaped Dr. Robinson's memory that the Warburg tincture also contains quinine sulphate, to which its therapeutic value is probably due, and although it contains also other ingredients, as angelica, zedoaria, camphor, etc., the tincture cannot be called *another* remedy as long as it also contains quinine, and in a quite considerable dose. If you eliminate any of the other ingredients, as you do, for instance, the aloes, the tincture retains its antiperiodic property; but without the quinine it remains only a mild aromatic bitter.

OUR LONDON LETTER.

(From Our Own Correspondent.)

MEDICAL STUDENTS AND MILITARY SERVICE—FOOD AND THE LAPDOG—PREVENTION OF VENEREAL DISEASE—A MEDICAL INSURANCE SCHEME.

LONDON, May 9, 1918.

MR. HAYES FISHER, president of the Local Government Board, made a statement in Parliament last week on the work of his Department, the usual formal opportunity being given by the necessity for taking a vote on supply. His remarks on the coordination of the health agencies of the country proved to be of considerable significance to the medical profession which is awaiting any official pronouncement with regard to the evolution of national health activities which will serve as an indication of the influence and position which the projected Ministry of National Health may be expected to enjoy. Mr. Hayes Fisher introduced the subject of public health administration by reference to the housing of the poor, which is reasonable, considering the influence that bad housing has alike on the dissemination and prevention and cure of disease; but to medical men the subject of bad housing has become rather tedious as it is an invariable prelude to a policy of do-nothing. When medical men press upon a community the value of notification of contacts in infectious diseases, of early treatment of conditions noticed in the children of the State schools, of the value of medical inspection of places like cinema halls and so on, and so on—to take three directions in which medical activity has lately been in evidence—the reply is too apt to be that while so large a percentage of the population lives in an unhealthy environment the amount of good that can be done by other preventive measures is negligible. With piety, it is added, that all energies should be directed towards the improvement of the housing of the poor and from that time forward nothing is done as the reform in the housing of the poor is soon found too difficult to tackle without Government support. Mr. Hayes Fisher, however, while urging that housing is the most important branch of public health administration at the present moment, pointed out that it was not possible to divorce health policy from housing and sanitation, thereby indicating that when national health becomes the especial care of a government department; government must set the housing of the poor in order. He spoke strongly in favor of a Ministry of National Health which

should bring all the health activities of the various State Departments of the country under one department and one minister, but he pointed out that it would not be sufficient merely to amalgamate the departments that now deal with various sides of the question, but that it would be necessary to look closely to the health administration in local areas to see that the overlapping which now exists was not perpetuated under the new scheme. Here Mr. Hayes Fisher spoke as one knowing well his medical politics, for in the present condition of the law the amount of overlapping possible is very great.

The position of medical students in relation to military service has been modified many times, but Mr. Beck, Parliamentary secretary to the Ministry of National Service, has now made an exact résumé of the situation for the information of medical schools, and the parents and guardians of the students concerned. Under a "National Service Instruction," dated last March, fit men who were at that date medical students at a recognized school, and who had passed the examination in their first professional subjects, are exempted from military service in certain conditions. Those conditions are the production, if necessary, of certificates proving industry and the joining of an officers' training corps so that their military education may accompany their professional one. On completing their second examination in professional subjects, they may, however, be summoned from their studies to serve as surgeon-probationers in the navy, for while the army has no use for any but fully qualified men, who are, theoretically at least, educated to go anywhere and do anything in an independent capacity, the navy gives valuable appointments to senior medical students who act as dressers, clinical clerks, and hospital assistants to the surgeons and physician of the fleet. This is not the only government regulation as to the position of medical students towards military service, for an "Army Council Instruction" has now freed from the military service which they were rendering all whole-time medical students, who had enlisted in a combatant capacity, but who had passed their first professional examination. The two instructions were badly needed, for the supply of qualified medical men was becoming very small.

There has been a growing feeling that dogs kept in the cities and obviously only for the indulgence of the sentimentality of their owners should be kept down in number by high taxation. These animals serve no purpose either as aids to the chase, as restrictors of mischievous vermin, or as protectors of property. They are a veritable luxury and as such should certainly be taxed. It is true that the food which they consume may be in the total negligible in proportion to that required by the crowded population among which they live; still they eat something, and that something might be better employed. The suggestion that the lapdog, pure and simple, should be killed off has been met with loud protests from one class of people, namely, those who hold that all medical research of an experimental nature is conducted with malignant devilry upon dogs—dogs in this connection are always alluded to as "the friends

of man." They speak of depriving a drawing-room of its "Pekinese," as though the cessation of its yaps would be one of the severest blows to society inflicted by the war. The idea that there should be no food for the lapdog makes them nearly as angry as the news that the Ministry of Food, under the Defence of the Realm Act, has made provision for the feeding of animals kept for the purposes of experiment. For an authority has lately been given to licensees under the Acts of Parliament which authorize and regulate vivisection to obtain the foodstuffs required for the animals used for laboratory purposes, this use of such material being open to government inspection and a record of the work being carefully kept.

The utility of the machinery which has been devised for the prevention of venereal disease in our Navy and Army is almost as much in question now as its morality. The regulations made under the Defence of the Realm Act at the close of last month provide that no woman "who is suffering from venereal disease of a communicable character or form shall have sexual intercourse with any member of the Navy or Army, or solicit or invite any member of these forces to have intercourse with her." It is thought that this regulation will insure that infected women are made clean by curative treatment in hospitals, or privately, but as a matter of fact the difficulty of convicting any woman of having broken the regulation will be well-nigh insuperable. It follows that where penalty is very unlikely obedience will not be strict. A Criminal Law Amendment Bill has also been introduced (or rather reintroduced) in the House of Lords, which measure, by using the words "no person" in place of "no woman" attempts to equalize the sexes in the matter of legislation against immorality, the bill in the House of Lords, however, being directed toward the population at large and not especially toward the protection of the Navy or Army. While the regulation under the Defence of the Realm Act has for its object the cleansing and keeping clean of infected women, some sort of official sanction is also being given to the provision of facilities for safeguarding the Navy and Army by protectives and prompt medical treatment. "Outfits" have been put up in parcel form at very low prices, and have been made available in certain circumstances for the sailors and soldiers. These should be of some service, but it has been rightly pointed out that too much stress must not be put upon the value of inunction and instillation of mercurial creams. Even with their use, infection may occur unless strict cleanliness is also observed, and especially among uneducated people the temptation is to trust too much to the magic of the drug and to neglect precautions which otherwise might have been taken. The difference of opinion among medical men as to the utility of these outfits is almost as acute as that between practical citizens as to their morality.

A meeting was held to-day (May 9) of the committee of the Medical Insurance Agency, the proceedings at which sufficiently showed the success following on the principles laid down by the Agency, as well as the debt for practical service which the Agency had contracted toward their secretary, the late Mr. Guy Elliston. When the Agency first made its appearance as little more than a suggestion in

the columns of the *Lancet* it was Elliston who saw the big business propositions which lay below it, and who immediately took the necessary steps to organize the movement with the cooperation from the beginning of the editors of the *British Medical Journal* and the *Lancet*. At to-day's meeting of the Agency the income and expenditure account for the year ending December 31, 1917, was submitted, and showed a surplus for the year's working of just upon £1,000. The fundamental idea of the Agency was that through a selected committee the medical profession should approach insurance companies, and, in the position of agents, should place policies with them on life, accident risks, fire risks, and so on, and should in return secure rebates to be distributed to the medical insurers, while giving all further profits to medical charities. The success with which this program has been carried out, even with the approach of the fourth year of war, is shown by the following figures. Just upon £2,000 was earned by commissions on premiums, of which over £700 was returned to those insuring through the Agency in the form of rebates; while £1,000 was distributed in medical benevolence, £500 going to the Royal Medical Benevolent Fund and its Guild; £200 to Epsom College, the public school which has provided such admirable gratuitous education for sons of medical men for whose education no provision could otherwise be made; and 200 guineas to a "War Emergency Fund." The Agency should, when normal times arrive, prove a very genuine economy to the more thrifty sections of the medical profession as well as a considerable source of profit to deserving medical charities.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

WORK OF THE SOCIETY OF FRIENDS—BRITISH RED CROSS—BRINGING THE BELGIAN CHILDREN TO PARIS—AN ATHLETIC ARMY.

PARIS, April 22, 1918.

THE Society of Friends is well named. Their object is to be friends to all who need friends, and the scope of their friendliness ranges from playing games with refugee children to building barns in the war zone. They have now three groups of men engaged in erecting the huts sent into the war zone from workshops at Dôle and Ornans. For the Somme there is one group, for the Aisne two groups. In the Aisne, 28 huts of two rooms each have been put up, in the Somme 23, making a total of 51 up to the end of January. The list does not include huts that have arrived from Dôle and are delivered to the sites but not yet mounted, nor those for which foundations have been prepared.

At Sermaize the Friends have a medical and relief center. This includes a temporary civilian hospital of 24 beds, and surgical hospital for civilians, two doctors, eight nurses and forty beds, together with general district practise by doctors and nurses. Also at Bettancourt-la-Longue, about five miles away, 50 to 60 sick and convalescent children are cared for by visiting doctors from Sermaize, and one doctor has established headquarters at Auzéville, well toward the lines. The work consists of two kinds: one agricultural, that is, threshing and repair and loans of farm implements in the district; the other, general relief—the distribution

of clothes and furniture and the giving of employment. For this the Friends have established an embroidery industry which is most successful, for not only does it provide paying work for the people, but the results turned out are beautiful as well as practical. The designs are made by the Friends themselves and are embroidered in bright-colored wools or silks on linen and made into towels, table covers, and stripes for decoration for clothes. At Châlons-sur-Marne there is a maternity hospital. Since the war began 600 babies have been born in this hospital. The month of January was a very busy one at Châlons, and on one occasion 95 out of 96 beds and cots were occupied. There were 23 births during the month.

The Friends are, moreover, able to turn their attention much earlier than usual to their spring work in the war zone. Ploughing with both horse and tractor has started whenever the state of the ground has permitted. The repairing of the Friends' own hay and harvest machines has begun, and they have already a large number of requests from French farmers in whose villages they have already done threshing that they should undertake the repair of farm machinery. The Friends have also arranged for a distribution of artificial manures at cost price, and have a truck load on rail, most of which has already been asked for. Requests for seed wheat, oats, and betterave seed, as well as for supplies of binder twine, oil, etc., on similar conditions, are continually coming in.

All this seems to show that the Friends' methods of work have been appreciated, and also points to the fact that the cooperative spirit is growing. This latter fact is of the greatest importance. It is now becoming quite an ordinary method of procedure for the Mayor to collect together the requirements of the whole commune, and thus order economically, through the Friends or direct, large quantities of seeds, fertilizers, etc., instead of each cultivator sending in his order separately. The Quakers have taken a disused blacksmith shop at Evres and hope to be able to start a gang of four or five men there for the repairing of machines, stocking of spare parts, and distribution of supplies. They have also started a gang at Auzéville. They are arranging to have a storehouse and a machine repair shop at Auzéville.

Recruits from America are still coming to join the Quakers and still the work is too big for the number of men on the ground. As France needs food, and the submarine peril is not yet abated, and as there is an unrelaxed need of additional farm labor, the recruiting of the agricultural army by these volunteers—whose tradition is against destructive war service, but not against constructive service in the war zone, even where the risks are liveliest—is welcomed by the French authorities. From all sides come demands for help, and some of them can't be filled because there are not enough men to go around; but wherever and whenever they can the Friends stand ready to help those who need help.

The British Chamber of Commerce for the Riviera is making a special appeal to residents and visitors on the Riviera in behalf of the British Red Cross, which has the approval of the joint War Committee of the Red Cross Society and the Order of

St. John of Jerusalem in England. The work of the British Red Cross is spread over Europe, Asia, and Africa, and involves an expenditure of £8,000 daily, and this outlay is still increasing. It benefits military wounded and sick from all parts of the British Empire, and in a secondary degree the sick and wounded of the Allies. It succors the wounded on the field and transports them to base and home hospitals. It maintains a gigantic system of transport and supplies, with stores and distributing centers, hospital trains and ships, and an army of motor ambulances. It has provided four hospital trains each carrying 450 men, at a cost of upward of £60,000. Fourteen hospitals, totaling 2,000 beds, have been established in France and Flanders, including three for the Allies, and more than a score of private voluntary hospitals offered to the French and the Belgians, are run, staffed, and supplied through the joint committee. The organization and maintenance of the supply and distribution of stores of all kinds involve an expenditure of nearly £1,000,000 a year.

More than fifty Belgian children have arrived at the Nouveau Foyer Ecossais, at Neuilly, from Switzerland, where they were evacuated by the desire of the Queen of the Belgians, by Miss Fyfe. These children are now being returned to their parents, some after an absence of three years. They were received by Miss Fyfe and Mr. Coleman, who represent the Friends, who, through the intermediary of the British Y. M. C. A., have established this home in Paris, where Miss Fyfe can continue to bring children from the Belgian front and also receive little "rapatriés" from Switzerland. Fifty other little Belgians will arrive from the front during the month of March, and will remain in Neuilly until all danger at their homes is over. The Duchess de Vendôme, who saw most of these children leave Miss Fyfe's foyer at the front, has visited the little ones at Neuilly. The Belgian Government will supply governesses to carry on the education of the children, as while learning French and English they must not forget their Flemish. Mgr. Marinier, aumonier-en-chef, will appoint a priest for the religious instruction of the children. The committee owes thanks to Mr. D. L. Blount for his advice and interest in the first negotiations, and likewise to Miss Della Saunders of Boston, Mass., for her untiring help throughout.

At home, American games and outdoor sports have a following of most of the American nation. It has been only natural, therefore, that, bent on such a serious mission, involved in a work that is imbued with such great responsibilities, we should participate in the same sports "over here" to relieve the growing tension and to freshen our minds and bodies and strengthen the fighting spirit that must be maintained to win. Boxing, wrestling, football, and basketball have been carried out on an organized plan, to the enjoyment and benefit of nearly every soldier overseas, and, as spring advances, baseball and tennis will hold the stage until fall. The American soldier wants sports, loves sports, and must have them. We are an athletic nation, and the fighting spirit aroused on the athletic fields will show in the final spurt in the biggest contest ever before staged in the history of the world."

MEDICAL WEEK IN CANADA.

(From a Special Correspondent.)

HAMILTON, ONTARIO, May 28, 1918.

THE greatest medical event that has ever occurred in Canada is now taking place in Hamilton. Since the beginning of the war medical meetings in Canada have been somewhat frowned upon and held in abeyance. However, it was decided that a medical congress on a large scale should be brought to pass and that its place of meeting should be the city of Hamilton.

The congress is a combined meeting of the Canadian Medical Association, the Canadian Association for the Prevention of Tuberculosis, the Canadian Public Health Association, the Ontario Health Officers' Association, and the Ontario Medical Association, under the auspices of the executive of the Ontario Medical Association.

The two first days of the meeting were devoted to public health matters. The opening ceremony was performed in the ball room of the Royal Connaught Hotel by the Duke of Devonshire, the Governor General of Canada, at 10 o'clock on Monday morning, May 27. The opening speech was distinguished by common sense. In the course of the speech he dwelt upon the fact that sanitation and hygiene have played the most conspicuous roles in the war. His Excellency further drew attention to another very obvious point, that one of the great problems at the present time and after the war is and will be the reconstruction, rehabilitation, and reeducation of the maimed and injured soldiers.

The first paper to be read was one entitled "Hints on Rural Administration," by Lieut.-Col. John W. S. McCullough, chief health officer for the Province of Ontario. In reality, Dr. McCullough's paper was given over to a consideration or rather synopsis of the act passed recently by the legislature of Ontario, with the view of controlling venereal diseases. It may be said, in passing, that the keynote of the Public Health meeting was the question of how best to deal with venereal diseases and of how best to conserve child life. The Ontario act for the control of venereal diseases is patently a long step in the right direction and is, perhaps, the most important effort to meet the venereal situation that has been attempted by any legislature. By the provisions of this act any person under arrest may, if considered necessary by the health officer, be examined to discover if he is suffering from venereal disease. If thus infected, he may be detained and treated. Medical men in charge of places of detention are required to report cases within twenty-four hours. Medical officers of health may also require examination and treatment of persons whom they know to be infected with venereal disease. In order to prevent unjust action against a physician making examinations or reports with regard to such cases, it is provided that action of this nature can be brought only with the consent of the provisional board of health. Provision is made for right of entry in the day time by the health officer or his deputy to premises for the purpose of inquiring or examination of persons known to be so infected. Hospitals designated by the board are required to provide facilities for treatment. Under pain of heavy penalties, no other

than qualified physicians are allowed to attend or treat sufferers from venereal disease. Penalties are also provided for those who advertise remedies or cures for venereal diseases, as well as for those found guilty of infecting others. Provision is made for maintaining secrecy. The regulations will come into effect on July 1.

In the discussion that followed this address, Dr. Peter Bryce of Ottawa said that the success of the carrying out of the act would largely depend upon the facilities provided by the 88 hospitals of Ontario which treat these cases. Expert diagnosis and cure were very necessary. Dr. Jacques of Jarvis stated that these diseases would be treated largely in hospitals, as it was exceedingly necessary that there should be expert determination of cure. Also, treatment should be free because it was for the good of the race and the State that this special plague should be eradicated.

Capt. H. W. Hill of London, Ont., president of the Ontario Health Officers' Association, then delivered the presidential address. He emphasized the importance of sanitation and especially of personal hygiene, and said that from the commencement of the war up to the present time, the result had been a triumph for sanitation and personal hygiene. He pointed out that formerly the health officer had been regarded with polite indifference as a necessary or unnecessary evil by the practising confreres, almost indeed, as an outcast; now he was fast coming into his own. There were three essential fields for public health work, those of venereal disease, tuberculosis, and child welfare. The other infectious diseases were of relatively small concern. Typhoid fever had been virtually eradicated, while diphtheria, scarlet fever, and so on were being eliminated. With regard to venereal diseases Hill thought that the crux of the problem lay in illicit intercourse. The women of the streets could be found and dealt with—incarcerated, although places of incarceration must be supplied by the government. But the case of the woman who worked and gave herself to illicit intercourse frequently or occasionally was a very different matter and one which required great consideration. So long as such a state of affairs existed there was little hope of eradicating venereal disease, for it must always be borne in mind that one infected woman can spread the disease far and wide. Hill insisted in the fact that a negative Wassermann test is no proof that infection is not present in the primary stage of syphilis. In fact, in the early stage of syphilis the Wassermann test is usually negative.

A paper was read by Dr. J. J. Harper on "Good Public Health Service in Small Towns and Rural Municipalities," and last of the papers of the day's session was one by Capt. Gordon Balec dealing with the venereal disease problem. The gist of his paper was that illicit sexual intercourse lies behind the whole question. Statistics available from military districts in Canada show that many, perhaps the majority of army cases were contracted previous to enlistment. While organized prostitution exists or existed on a somewhat large scale in Canada, that since the war began, it has been chiefly by the agency of young girls who work in the day that infection has been spread. Bates said that news-

paper publicity had done much towards suppressing the evil, and that education by every means available should be resorted to in order that the greatest single menace to health and therefore efficiency should be, at least, controlled as far as was possible.

In the discussion that followed the reading of the papers by Hill and Harper interest appeared to center mainly on the question of disinfection after recovery from infectious disease. Some of the speakers were enthusiastic regarding the results from disinfection after scarlet-fever with formaldehyde and permanganate of potassium. Hill, on the contrary, went so far as to say that so far as infection from scarlet fever was concerned, if he detected any discharge from the ear or even if there was a herpes that he considered infection transmissible and refused a patient in this condition. He, moreover, averred that he had not followed disinfection for scarlet fever for some years. The theory as to the infection being air-borne is not actually defunct, but is dying fast, and with the disbelief in the means of conveyance, the value of disinfection has also fallen into disrepute. So warm did the dispute wax as with respect to the merits of disinfection after scarlet fever, that it was determined to appoint a commission in Ontario to investigate into and report on the employment of quarantine and terminal disinfection.

3. **Differential Diagnosis in Psychiatry: A Comparison of Methods in Various Disease States.**—Lawson G. Lowrey has found that a most useful division of mental activities is that into the sensorium-intellect and emotions-will. Thus, those mental states in which the symptoms are primarily and predominantly in the sensorium-intellect field are clearly related with the toxic-organic-epileptic disease processes; whereas the disturbances primarily and predominantly in the emotion-will field are related to the schizophrenic-cyclothymic-psychoneurotic-psychopathic group of disease processes. Hence, it is necessary to differentiate with great care between primary and secondary effects in any mental state, and to determine the degree of disturbance in all fields. He defines primary symptoms as those common to all cases of a particular group; and secondary symptoms as those which occur in some, but not all, cases of any group. The primary symptoms are not always predominant and in some cases are only detected with difficulty because of the greater rôle assumed by the secondary and rare symptoms. It is in such cases that the difficulty of diagnosis is greatest. All these various points must be borne in mind—the analysis and interpretation of symptoms; the conception of states, with primary and secondary phenomena; the necessity for careful and complete analysis of the whole individual; the relationship of states to causal processes; and the scientific importance of symptomatic (as opposed to termination) diagnoses. Lowrey points out the importance of accuracy in diagnosis; it is better, for instance, to leave a case undiagnosed than to pronounce it one of dementia precox. If this disease

is to stand as a psychiatric entity it must have a recognizable symptomatology; moreover, precox is not the only disorder whose sequence is dementia. The aim must be to arrive at rapid and thorough differential diagnosis by rapidly narrowing down the diagnostic field to a few possibilities, and then finding the characteristics which permit accurate diagnosis. The differential diagnosis between groups is to be based on special signs and symptoms of each. Thus in paresis, senile dementia, arteriosclerotic and chronic alcoholic psychoses, in some of the somatic cases and in epilepsy, the primary symptoms are disturbances in the retentive field (of memory) combined with certain disturbances of attention and assimilation and often of consciousness. In paresis, the pupils, reflexes, speech, and handwriting must be considered; delusions of grandeur, euphoria, etc., are very characteristic when present. Senile dementia is characterized by loss of recent memory, with retention of remote memory, disorientation, restlessness at night, forgetfulness of immediate happenings, and conduct disorder—and so on. In the second large group, i.e. the acute alcoholic (with the important exception of acute alcoholic hallucinosis), other acute toxic psychoses of exogenous origin, severe meningitis, etc.—in general, the acute “fulminating” group—we have to do with active symptoms in the field of consciousness and perception. It is therefore important to know the immediate history and physical state of the patient; temperature, pulse, and respiration; result of lumbar puncture, blood examination and urine analysis. This constitutes a practical program for the speedy determination of the cause and the commencement of active treatment. It must be remembered that not all physical diseases are capable of producing mental disease, and that mental disease of any type may coexist with almost any type of physical disease. In the establishment of etiological factors the mental disturbance must be of the type which the somatic disease ordinarily causes, and atypical cases may be included only after the most searching and rigid analysis. It is important to realize that confusion and amnesia characterize the organic group, whereas confusion, circumscribed amnesia and hallucinations characterize the toxic group, with epilepsy sometimes in one group and sometimes in the other. The complicating factors in diagnosis lie in the fact that emotion-volition disorder occurs in psychoses belonging to any group, and the conduct may be quite similar in groups of widely varying etiology. The essential points of differentiation lie in the state of consciousness and in the memory, together with an analysis of the fitness of conduct to ideational background. The schizophrenic states are more complex, and here again the emotion and will disturbance is the predominant feature—here the emotions and will disturbances do not correspond. With a clear consciousness such cases are hallucinated, giving the impression of clouding and memory loss; they are, nevertheless, oriented and without particular memory defect. The essential point to recognize is that clouding of consciousness and intellectual disorder are not characteristic symptoms of the precox process—and we must hesitate to make such a diagnosis where symptoms are not in the emotions and will. In the psychoneurosis it is a question of disorders of emotion and will, and not intellectual disorders. In the dream states there is partial or complete dissociation of the personality. An analysis of the psychopathic cases shows that the causes lie in improper relations of emotion and will. In acute alcoholic hallucinosis the disturbance of consciousness is absent; typical cases resemble dementia precox closely and the question arises whether they may not be toxic dementia precox; here the history is of the greatest importance. Finally there is one great group of cases in which the disorder is chiefly intellectual—these are the paranoid states (omitting paranoid dementia precox, where the important thing is the precox disturbance). In such cases there is no consciousness disturbance and no disturbance of retention and recollection, but there is marked judgment disorder. Finally, the author points out that accurate differential diagnoses can be made only if the observations are detailed and thorough, and if the examiner interprets correctly and properly aligns the symptoms with causes.

1. Hyperacidity of the Gastric Secretion as a Prime Factor in Attacks of Angina Pectoris.—H. Iloway reports in detail several cases of angina pectoris, in all of which hyperacidity of the gastric secretion was shown by an examination of the chemismus of the stomach made after an Ewald and Boas test breakfast with a bland meal taken the previous evening, and usually a glass of milk before retiring. The writer points out that the cases here reported may explain the anachronism of an epigastric or abdominal angina pectoris, both an impossibility. He refers to the statement made by Latham that angina pectoris is a spasm, a cramp of the heart, excited by the hyperacid gastric juice through the filaments of the vagus; a fact which should not appear strange to any one familiar with the violent spasms excited by hyperacid secretion in spasmodic closure of the pylorus. This view as to the cause of cardiac spasm makes it apparent that it may supervene in any and all the various forms of cardiac disease, which explains the many contradictions set forth by Allbutt. It makes clear the intercurrent disturbances occurring in the epigastrium and abdomen, which are not at all due to the angina and which are frequently seen in cases of gastric hyperacidity in which no angina exists. It comports fully with the etiological factors mentioned by Allbutt, Huchard, and others, and explains the baneful effect of tobacco in such cases. It also accounts for the excellent results obtained by Trousseau by treatment with massive doses of sodium bicarbonate and extract of belladonna. It may furthermore explain the deaths which supervene suddenly in persons suffering from angina pectoris after a full and liberal meal—caused by a sudden outpouring of excessively acid gastric juice which excites a violent tonic spasm of the heart, an arrest of action beyond restoration. But what is of the greatest importance is the hope thus held out of being able to relieve the pain, the *angor animi*. Instead of the administration of nitroglycerine tablets as a palliative measure, the patient will be taught how to reduce the hyperacidity of the gastric juice and to keep it within normal limits, as well as how to reduce the hyperirritability of the gastric mucous membrane and of the nerve filaments distributed throughout it, produced by the hyperacidity.

2. **Dysentery Bacilli: the Differentiation of the True Dysentery Bacilli from the Allied Species.**—Major F. W. Andrewes has examined upward of one hundred strains obtained from France and from dysentery hospitals in England with a view to determining the significance of the atypical forms frequently met with in the bacteriological examination of cases of suspected dysentery. He points out that although the short study made of the dysentery group is incomplete, it has been thought advisable to bring forward the conclusions which seem to emerge at this stage, not only for the assistance but more for the criticism of other workers on the subject. Should the conclusions be confirmed by others a distinct step in advance will have been made, since it appears that a large proportion of the forms which have masqueraded as atypical bacilli can readily be distinguished by appropriate tests. Andrewes points out that the great majority of such atypical forms fall into three species or groups of species, and for these he suggests the provisional names of *B. ambiguus*, *B. alkalescens*, and *B. dispar*, or lactose fermenting forms. The first two species may be rejected as having nothing to do with dysentery; *B. alkalescens* was found to be devoid of pathogenicity and *B. ambiguus* of low pathogenicity for the rabbit, although the experiments made were too few in number to be conclusive. In regard to *B. dispar* the author believes that more work is necessary; he found that these organisms possessed considerable pathogenic power for the rabbit, although their relation to human dysentery is yet unproven. There is a general belief that the lactose fermenters can be excluded in dysentery work, and Andrewes believes this is probably so; at any rate, they cannot be returned as dysentery bacilli. A certain proportion of aberrant forms still remain to be accounted for and some of these may really be atypical members of the Flexner-Y group, but such a residue would be very small. The acid-agglutination test, being both simple and rapid, Andrewes believes to be of great practical value in routine laboratory work. He thinks it hardly too much to say that it will do what no one specific serum can do, and that the margin of error is perhaps less than when even a number of specific sera are used. He further makes the following comments. Before returning a dysentery bacillus as inagglutinable it is always desirable to pick out a colony, pass it through a few daily subcultures in broth, and then formalinise the last broth culture and keep it for a few days in the cold. Some strains, which at first agglutinate poorly, come down freely after such treatment. Again, in returning a bacillus as agglutinable it is desirable to state whether it agglutinates to the full titer of the serum or only to half or a quarter titer. In order to do this it is necessary for the worker to have tested for himself the titers of the sera which he uses by the actual method that he is accustomed to employ. A given serum will differ widely in the results it yields with varying techniques and the titer stated on the bottle may give an erroneous impression. The method employed should be mentioned in the returns. Finally it is greatly to be desired, in the case of all doubtfully pathogenic forms isolated from cases of suspected dysentery, that careful observations should be made on the agglutinating power of the patient's serum upon the organism isolated as this is an important link in the chain of evidence.

3. **The Etiology and Treatment of "Trench Foot."** (A Report to the Medical Research Committee).—Major Joshua E. Sweet, Major George W. Norris, and Lieutenant Harry B. Wilmer point out that the usual classification of "trench foot" is based entirely upon a clinical picture and that the usual conclusion is that the disease starts from the outside, the consequence being that the treatment, as a rule, is purely local. They offer evidence to show that the disease commences from the interior, and that the infections which often mark the course of the disease are naturally secondary manifestations of the reaction of devitalized tissues to infective agents; that, therefore, the treatment should be directed to the skin only in so far as these secondary infections have resulted in surgical conditions. The resemblance of the condition to that known as Raynaud's Disease suggested the possibility of vasomotor

disturbance. The authors found that there was a marked increase in the blood pressure in "trench foot," as determined by the usual clinical methods, compared with that in the arm. The readings were made with two different types of sphygmometer, with the patient recumbent and relaxed, first upon the leg and then upon the arm. The auscultatory method was employed, the systolic pressure being read at the first regular appearance of sound, and the fifth phase being chosen as the diastolic criterion. (As there was some uncertainty as to the diastolic readings in the leg, the authors attach more importance to the systolic readings, which they believe to be clinically accurate.) Fifty-three patients were examined in this way and, in addition, eight controls. In one out of the 53 cases only the arm pressure exceeded the leg pressure, but after forty-eight hours it reverted to the condition found in the other 52 cases, in all of which there was a very definite increase of the leg over the arm pressure. In the controls the pressure was equal in the arm and the leg. It was also found that the increase in pressure was in direct proportion to the severity of the case and dropped as the patient's condition improved. These authors therefore conclude that trench foot is a disease incited by the effect of cold and inaction upon a foot whose vasomotor system is physiologically impaired. They believe there is a spasmodic contraction of the arterioles of the foot, the first result of which is ischemia with numbness, tingling, and burning pain; this is followed by a disturbance of the capillary circulation, perhaps due to lack of pressure from the veins, perhaps to the loss of rhythmicity of the driving force, perhaps to mere stagnation, with swelling of the foot from edema and diapedesis of red cells. This results in devitalization of the skin and favors infectious processes, which may extend to actual gangrene. Sweet, Norris and Wilmer found that the administration of potassium iodide in 20 grain doses (or in some cases 30 grain) three times a day resulted in decided relief from pain in twenty-four hours after the first dose had been given. In many cases there was a coincident fall of pressure, an average drop of the leg pressure of 10 to 15 mm. In all the cases so treated (31) the drug was withheld for twenty-four hours, and without exception this resulted in increased pain and insomnia. These authors believe potassium iodide to be of greater benefit than any other drug in the treatment of this condition, and point out that the relief from pain is absolute and the duration of the attack markedly shortened.

1. **Abstract of an Address on the Symptoms Which Precede and are Associated with General Arteriosclerosis (Being the Annual Oration of the Hunterian Society, Delivered on February 20, 1918).**—O. K. Williamson discusses in particular the cause and symptomatology of the hyperpietic form of arteriosclerosis as classified by Sir Clifford Allbutt. He points out that high arterial blood pressure is one of the earliest signs of arteriosclerosis, and is probably the cause of the process. In this connection the author refers to certain observations carried out by himself which would seem to prove that the occurrence of the arterial change is of later date than the rise of blood pressure. He gives the characteristic features of the

pulse of high arterial pressure as described by Mahomet and emphasizes the importance of persons of and beyond middle age having their blood pressure measured at intervals in order that arteriosclerosis may be prevented. He refers to the possibility, in exceptional cases, of the occurrence of diastolic before systolic pressure. Williamson describes the symptoms of hyperpiesia as heaviness, oppressive fullness in the head, or actual headache, pulsatile in character; drowsiness, insomnia, fatigue, especially in the morning; despondency, giddiness, memory failure, noises in the ears, neuralgic attacks, nervousness; local areas of coldness or local syncope of the extremities, tendency to dyspnea, etc. Other symptoms may occur which may possibly be accounted for by the conception of arterial spasm, which will be considered later. By diagnosis and judicious treatment much can be done to prevent the development of arteriosclerosis. In its early stages the general nutrition is good and there is often a tendency to fatness. In addition to the symptoms described by Mahomet, the pulse may show an extra systole which is usually of ventricular origin and may occur at every second beat, in which case it is necessary to distinguish the condition from *pulsus alternans*. The heart usually shows signs of hypertrophy. As pointed out by Mott, the nervous system may suffer from partial or complete ischemia, or there may be attacks of maniacal excitement or depression. Williamson then takes up the question of localized arterial spasm, citing cases which show that it may occur in superficial arteries. He points out that the first suggestion of arterial spasm as an explanation of cerebral seizures was made by Peabody. The subject was further studied and cases cited by Russell and Edgeworth, and finally Osler placed these cases in the three following categories: (a) Healthy individuals with high blood pressure, without signs of arterial disease. (b) Patients with well-marked arteriosclerosis, in whom the cerebral attacks have come on without warning, sometimes as the signal symptom. (A majority of Williamson's cases come in this group.) (c) In advanced sclerosis with cerebral changes, manifested by progressive mental and muscular weakness, all possible types of these transient seizures, including convulsions, may occur. The attacks are most frequent in the aged, but men in the fifth and sixth decades are also affected. The author would amplify this classification by the addition of a fourth class, to include cases without signs either of arterial disease or of high blood pressure. Russell has shown that an attack of angina pectoris may owe its incidence to a reflex action originating after a meal, for it is known that following the ingestion of food a contraction of the systemic arteries takes place. The French neurologists, especially Dejerine, Sollier, and Grasset, described a syndrome explicable by intermittent spasm of the arteries of the spinal marrow—the "*claudication intermittente de la moelle épinière*," which is almost always syphilitic. Williamson goes on to say that, once admitting the existence of arterial spasm in one locality of the body, we cannot reasonably refuse the application of the theory to explain symptoms in other parts of the body, such as, for instance, attacks of abdominal pain. The hypothesis is one of no mere academic interest, but holds out full hope of the prevention of most dire effects. He adds that in making a diagnosis the symptoms of hyperpiesia must be distinguished from those of neurasthenia and a careful personal and family history is therefore of the greatest importance. The author concludes with a hopeful comment on the present food situation—he believes that the enforced abstinence from an excess amount of protein food cannot fail to exercise a favorable influence on the incidence of one of the most insidious and crippling diseases of modern middle life.

Berliner klinische Wochenschrift.

March 11, 1918.

The Specific Treatment of Infectious Diseases, with Particular Reference to Tuberculosis.—A. Feldt offers an analysis of the notion of "specific therapeutics." In opposition to a generally accepted opinion, it cannot consist in a direct attack on the pathogenic agent.

This interpretation is difficult to defend in the case of Hg. and lues and quite out of the question in the case of the action of salicylic acid on rheumatism of the joints. "Specific therapeutics" is an essentially clinical notion, and may be defined as "the use of chemical bodies which increase the production of normal specific antibodies, bringing about a cure of the histological morbid products (inflammations, granulations) and rendering the pathogenic agents inoffensive; all this with doses which not only are not toxic for the cells, but even exert a stimulating action on them (metallic preparations, for example)." Passing next to the study of the action of gold on tuberculosis, the writer opines to the belief that these conditions are fulfilled by "Khysolgan." The gold exhibited accumulates in the diseased tissues, reaching them by way of a paravascular route. The metal sets up focal reactions, which may result in the cure of the process: In point of fact an accelerated autolysis occurs in the morbid focus along with a fibrous reaction in its neighborhood. Thus the bacilli are isolated, although not in reality destroyed. Gold acts essentially by favoring an autolysis of the diseased structures by catalysis.

A New Treatment of Typhus Fever.—K. von Zielinski, being inspired by the excellent results obtained by autoserotherapy in pleurisy and ascites, has injected the cerebrospinal fluid removed from patients seriously ill with typhus, the fluid being withdrawn from the patient himself and then injected. The dose was increased until 15 c.c. was reached. The injections were first given subcutaneously, afterward intravenously. The writer, who selected patients seriously ill with typhus, in which the prognosis was absolutely bad, declares himself well satisfied with these preliminary essays with this treatment.

Intravenous Administration of Camphor.—H. Leo recalls the fact that there are many drawbacks to the usual method of introducing camphor into the system, namely, a very slow and often incomplete absorption, and the very small amount of the drug which enters the circulation. The favorable action of the medication, namely that of a cardiopulmonary stimulant and antipneumococcic, likewise favoring pulmonary irrigation, should cause one to prefer its administration in an injectable form. Leo advises intravenous injections of a saturated aqueous solution of camphor, Ringer's saline solution being used as a medium. The amount of camphor injected each time varies from 10 cg. in 75 c.c. solution to 30 cg. in 300 c.c. water, to which 1.5 cc. alcohol is added. The total amount of camphor utilized is thus reduced without interfering with its effective physiological action. The solution is prepared by simply shaking powdered camphor in Ringer's artificial serum, the resulting concentration being 0.142 per cent. The addition of alcohol or ether increases the solubility, but is not to be recommended.

The Diagnosis and Treatment of Trichinosis.—S. Schoenborn points out the importance of the eosinophilia, which is absent in typhoid or dysentery. The edema and neuromuscular phenomena are of secondary importance. The surest diagnostic method is a biopsy of the muscles. A bit of muscle is excised and the parasite or its embryo can be detected, a fact which is exceptional in the case of the feces or blood. Salvarsan has no therapeutic effect on the disease. On the other hand injections of strychnin appear to shorten the duration of the affection.

Wiener medizinische Wochenschrift.

March 30, 1918.

Pityriasis Rubra (Hebra).—G. Nohl discusses a case and insists particularly on two phenomena presented by the patient, namely, a total alopecia and reticulated melanodermy. The pigmentation is the result of changes arising in the basal layer of the epidermis. A hyperactivity of this layer also takes place, making itself evident by an excessive formation of "melanotic ferments," according to B. Bloch's conception.

Book Reviews.

MANUAL OF LABORATORY DIAGNOSIS. By STELLA M. GARDNER, M.D., and MARY C. LINCOLN, Ph.B., M.D. Formerly Assistant Professors of Laboratory Diagnosis, College of Medicine, University of Illinois. Price, \$1.25. Chicago: Medical Book Company, 1917.

PROBABLY there is no subject in the domain of medical literature that receives more attention than that of laboratory diagnosis. due no doubt to the great advance which has been made in this branch of the medical sciences in the past decade. The number of small guides or manuals such as the present one, already published, is legion and, while it is a commendable undertaking to abbreviate books on laboratory procedures as much as possible, there is always the danger of sacrificing efficiency and thoroughness for the sake of brevity. The manual before us has this fault. It treats rather superficially of the clinical laboratory examination of blood, urine, stomach contents, feces, human milk, spinal fluid, and sputum, with a fair consideration of the technique of the Wassermann reaction. Some typographical errors are in evidence and the subject matter as a whole is indifferently assembled. The most that can be said for it is that no gross or flagrant misstatements are present.

MEDICAL DIAGNOSIS FOR THE STUDENT AND PRACTITIONER. By CHARLES LYMAN GREENE, M.D., St. Paul, etc., etc., etc. With 14 Colored Plate and 548 Other Illustrations. Price, \$10.00. Philadelphia: P. Blakiston's Son & Co., 1917.

THE fourth edition of this text has been recast and extensively amplified so that its present status represents practically a new volume. From the retrospect of twenty-five years' clinical and teaching experience the author has produced in this edition a comprehensive work on modern diagnostic methods which reflects credit on his ability as a lucid, scholarly writer and on his wide grasp of the subject. In the beginning certain fundamental principles of diagnosis are discussed and considerable space devoted to case-taking, the significance of outward signs of disease, analysis of subjective and objective symptoms, and the importance of approaching the diagnostic problem with an open mind. The bulk of the book is given over to an exhaustive description of the various physical, instrumental, and clinical laboratory methods of diagnosis, which are taken up in a systematic manner. The immense amount of information contained in the volume can be gathered from the fact that it comprises 1203 pages printed on rather thin paper. Numerous illustrations are interspersed throughout, and serve to supplement the context. The employment of italicized sentences and paragraphs, as well as leading marginal designations, focuses attention on the important details. Finally, and probably what is most essential in a book of this type, there is an unusually extensive and complete index. We can recommend this edition as a thoroughly sound and up-to-date treatise on medical diagnosis.

BIRTH FRACTURES AND EPIPHYSEAL DISLOCATIONS. By EDWARD D. TRUESDELL, M.D., Assistant Attending Surgeon and Roentgenologist at the Lying-In Hospital, Associate Surgeon at the St. Mary's Free Hospital for Children, New York. Price, \$4.00. New York: Paul B. Hoeber, 1917.

THIS work covers an almost virgin field and will serve to correct the popular misconception of the ratio of dislocations of the epiphyses to fractures in the newborn, and as to the type of fracture when that does occur. Most doctors firmly believe that separation, or dislocation, of the epiphysis is a rather common injury in the newborn, and also that when fracture does occur it is frequently of the greenstick type. Truesdell, however, in studying practically all the cases of fracture and epiphyseal separation that occurred in the course of more than 33,000 deliveries, found but eight in which epiphyseal separation occurred, while of the several hundred cases referred to the x-ray department of the Lying-In Hospital because of possible birth injury, not a single case of greenstick fracture of a long bone was found. Truesdell found 39 fractures

of the humerus, "between 25 and 30" fractures of the clavicle, and 13 fractures of the femur. All of these were frank fractures, either transverse or oblique. One interesting observation in connection with the 39 fractures of the humerus was that accompanying every fracture some degree of musculospiral nerve paralysis was noted, indicated by a distinct wrist-drop. Illustrative cases are reported in detail and the book is profusely illustrated by excellent Roentgenograms, some of which show the progress of individual cases at intervals of weeks, months, or even, in some few cases years. Methods of treatment that have been found most useful are described and illustrated. The difficulties which had to be overcome in studying these cases are pointed out and one can easily see that an immense amount of time and painstaking care have been expended in the preparation of this monograph. Truesdell's book not only throws a new light upon this important subject, but should stimulate greater interest in the early recognition and proper handling of these injuries.

THE SURGICAL CLINICS OF CHICAGO. Vol. 1, No. 6; December, 1917. Octavo of 244 Pages, with 89 Illustrations. Published Bi-monthly. Price per Year, \$10.00. Philadelphia and London: W. B. Saunders Company, 1917.

THIS is the final number of the first volume of these books and contains complete indices in addition to a rather more than usually interesting series of articles. There are fourteen contributors to this number and all of the articles are well worth reading. Worthy of especial mention are articles discussing tuberculosis of the kidney, the technique of prostatectomy, and clinical lectures based upon cases of actinomycosis of the colon, cancer of the rectum, and fractures. The Surgical Clinics of Chicago, following the lines of the original Murphy's Clinics, have presented during the past year 1325 pages of text with 496 illustrations. The contributors, forty in number, have included many of Chicago's leading surgeons and a wide range of subjects have been covered. While some of the articles have been rather crude, the general average has been good and the completed volume should be of value to any progressive surgeon.

THE IMMEDIATE CARE OF THE INJURED. By ALBERT S. MORROW, A.B., M.D., Clinical Professor of Surgery in the New York Polyclinic; Attending Surgeon to the Workhouse Hospital and to the Central and Neurological Hospital; Major, Medical Department, Officers' Reserve Corps of U. S. Army. Third Edition, Thoroughly Revised. 12 mo of 356 Pages, with 242 Illustrations. Price, \$2.75. Philadelphia and London: W. B. Saunders Company, 1917.

THIS is a very interesting volume. The book is divided into three parts. Part I should give one a very good superficial knowledge of anatomy and physiology. In Part II common forms of roller bandages are described and illustrated, as are also the various handkerchief and tailed bandages, materials, and methods of preparing dressings, etc. The application of heat and cold in the form of packs, poultices, etc., the giving of enemata, methods of disinfection, and almost innumerable other useful procedures are described and often illustrated. Part III, comprising about half the book, is devoted to the consideration of accidents and emergencies. Hemorrhage, contusions and wounds, burns, fractures, dislocations, sprains, asphyxia, poisoning, the transportation of the injured, and the preparation of the house for an accident case are among the subjects discussed—all in a very practical way. There are but few cases where one might consider that the simplest and best method of emergency treatment had not been indicated. Why, for example, in describing methods of reducing a dislocated shoulder, is the thoroughly reprehensible foot-in-the-axilla method described, and the usual and far safer Kocher method omitted?

In the words of the author, "This book is not intended to supplant the physician or surgeon, but is designed solely as a guide in emergencies until the arrival of medical aid or when such aid cannot be procured." Morrow's book well fulfills this purpose and should form an excellent guide to the layman or even the professional nurse.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-third Annual Meeting Held at Atlantic City, N. J., May 7 and 8, 1918.

DR. F. H. WILLIAMS OF BOSTON, PRESIDENT.

First Day—Tuesday, May 7.

Instructions in Treatment.—Dr. F. H. WILLIAMS of Boston delivered this, the presidential address, taking as his subject the instruction of students on points in therapy and pharmacology, known to the older practitioner, but which were outside of the student's experience. The young practitioner had many difficulties in adapting the details of pharmacology and therapeutics to practice. Students should be taught by men with long clinical practice and in that way they would learn to bridge the gap between *materia medica* and therapeutics on the one hand and the practice of medicine on the other. In the field of surgery the young surgeon was allowed to watch and to assist at operations, he learned the practical application of splints and other technical details. The same line should be followed in medicine. The field was not so dramatic as that of surgery, but more opportunities for bedside instruction should be offered. The student should be taught when to give powerful remedies and when not. The proof of the necessity of this method of teaching was seen when students were asked to prepare papers outlining treatment in a certain given case. The papers fell into three groups: (1) good; (2) incomplete; (3) with serious mistakes. The student and the young practitioner should learn how many resources medicine had at command, lack of knowledge of which was sometimes very culpable. The man who could bring sleep to the patient without resorting to hypnotics, or alleviate pain without prescribing morphine, in other words, who could accomplish results by simple means, was learning to be past master of his art. The experienced practitioner now understood that nature must do most of the work, but that she needs help, and that the wise physician could give now more than ever before, so that one could say that in the progress of two or three generations from now, it would be a still greater privilege to be a physician.

Results from the Intravenous Use of Salvarsan in Syphilis of the Nervous System.—Dr. BERNARD SACHS of New York read this paper. He said that at this critical period of the national life it was important to consider the treatment of a disease which so often maims and so rarely kills. The object of the communication was to put before the medical profession the views regarding the various methods of treatment. The paper was based on results of analyses of 400 cases at Mt. Sinai Hospital treated intravenously with the Philadelphia preparation of arsenophenamin which had proved entirely satisfactory. The views of Dr. Sachs upon the superiority of the intravenous method had been opposed by Dr. Fordyce who had stated that . . . "if the views of Dr. Sachs are final, an enormous amount of harm will result, as many victims of syphilis of the central nervous system will be deprived of their hope of recovery." Dr. Sachs said he felt convinced that much more good would be accomplished by the intravenous treatment, which could be said to be safe in the hands of the majority of physicians. All biological tests should be used as corroborative evidence and clinical evidence should not be disregarded. It could be said that the lack of serological evidence did not always disprove syphilis, nor was there a parallel between clinical symptoms and serological findings as remissions were often observed without serological change, and serological improvement was not always accompanied by clinical betterment. It was only in types with vascular lesions that the clinical findings and serological tests progressed *pari passu*. Of general paresis and tabes it could be said that the chief lesions were deep in the brain and cord, far removed from the spinal fluid, and only to be reached by the blood stream. In the meningomyelitic type of involvement it was impossible for the curative substances to remain in the fluid long enough to do any good. The doctrine of the

impermeability of the choroid plexus was refused. The pressure in the cerebral capillaries being higher than in the fluid, a metallic substance like salvarsan was rapidly absorbed into the venous system, therefore, why should the venous system not be used at once? Intraspinal medication, it was stated, was theoretically and essentially unsound. It was fatal to the syphilitic organism, but frequently also to the patient. Early and intensive treatment was necessary, as many doses as one every other day for 4 to 6 weeks, followed by a period of complete rest, were necessary. Forty or fifty injections might be required within a year. It would be impossible to introduce toxic substances so frequently into the canal. The advantages of the intravenous method were shown in the improvement of such syphilitic symptoms as headaches, palsies, epilepsies, and vascular symptoms. The type of case with spastic rigidity, rather than paralysis, showed least improvement from beginning to end. No claim could be made for the cure of tabes dorsalis or general paresis by the intraspinal method, the most that could be said was that remissions might be longer. It had been claimed that the neurologist did not see early cases, but it was precisely the neurologist or the psychiatrist who made the early diagnosis. It was therefore urged that treatment be begun as early as possible, and continued for years after the initial lesion and that the patient be kept under medical control for as long as necessary. The hope of the future would be the discovery of a substance less toxic than salvarsan with which a more intensive treatment could be undertaken.

Dr. S. J. MELTZER of New York said that there were a few points he would like to bring out—the first was in regard to permeability or impermeability, the essential thing was that there was no exact knowledge as to degrees of permeability. Benedict had found salvarsan in the spinal fluid, but no doubt not in such quantities as if injected intraspinal. Dr. Swift's work was conservative and he had never overemphasized his claim. It could be said too that Dr. Swift used not merely salvarsan, but salvarsanized serum, which was a different thing. Was there, Dr. Meltzer asked, any objection to giving intraspinal treatment at the same time provided it did no harm? Dr. Sachs had stated that Halliburton had given up the method. Dr. Meltzer said he would be more satisfied if Dr. Sachs had quoted Mott. If Dr. Sachs had seen no definite harm done there was no reason why both methods should not be used, and an agreement between the two factions brought about. With meningitis both intravenous and intraspinal injections should be used. If Dr. Sachs could not state positively that he had seen harm result in any particular case, there could be no objection to the use of both methods combined.

Dr. WILLIAM H. PARK of New York said that in regard to tetanus antitoxin, one could absolutely show that the intraspinal injection would protect and cure, while the intravenous alone would not. The two were given simultaneously.

Dr. SACHS, in reply to Dr. Meltzer, said he had distinct experience of the far more dangerous character of the intraspinal medication. If his word carried any authority he would advance that authority in support of his statement. In innumerable cases the intraspinal injection had accomplished nothing, but had caused great misery to the victim. He had seen immediate paralyses ensue and cases where rectal and vesical control had become markedly impaired. With the use of the intravenous treatment he had kept a patient over ten years in a very comfortable condition. At first he had been an advocate of the intraspinal but he had become firmly convinced of the necessity of giving salvarsan intravenously with unusual frequency and since that could be done harmlessly by the intravenous method, and also considering the dangers of the intraspinal he had come to prefer the former method of treatment; as important biological changes could be wrought by the intravenous method as by the intraspinal. The safety of the public at large demanded that this manner of medication be used to the utmost and the intraspinal left to those who had a special fondness for it.

The Relation of the Chemical Structure of Opium Alkaloids to Their Action on Smooth Muscle, and the Pharmacological and Therapeutic Properties of Some

Benzyl Esters.—Dr. D. I. MACHT of Baltimore made this presentation. For 4 or 5 years he had made an intensive study of the papaverine in connection with morphine. A marked difference was found in the two products. There was a difference in the effect upon the respiratory and the vomiting centers. The alkaloids of opium acted upon the central nervous system, upon peripheral structures, and upon smooth muscle. The effects upon the ureter of both the morphine group and the papaverine group were studied. The effect of morphine was increased tonicity, that of papaverine was relaxed tonicity and inhibition of contractions. Thus papaverine could be used for expulsion of renal calculi by relaxation of the ureteral muscle. Search was made for non-toxic products and benzyl benzoate and benzyl acetate, slightly toxic products were found, giving the effects of papaverine. Metabolic studies showed that benzyl acetate was excreted by the kidneys as hippuric acid. This was non-toxic and could be administered by the mouth. It had been tried clinically, but the disagreeable odor and digestive disturbance after its administration would contraindicate its use. Benzyl benzoate was then tried. It was found to be of use in cases of excessive peristalsis, and in diarrhea and dysentery remarkable results had been obtained. A 20 per cent. solution in alcohol was used. Other indications were in pylorospasm, intestinal colic, spastic constipation, biliary colic, ureteral calculi, vesical spasm, spasm of seminal vesicles, uterine colic, arterial spasm, high blood pressure, and lastly bronchial spasm with true asthma, in which remarkable relief was afforded. Benefit was caused by relaxation of spasm.

On the Use of Benzyl Alcohol as a Local Anesthetic.—Dr. D. I. MACHT of Baltimore read this paper which was the extension of his studies on the papaverine group of alkaloids. The benzyl esters being excreted as hippuric acid, it was thought that they would pass through the alcohol stage. Benzyl alcohol was therefore studied. The results were not what was expected, as regards its therapeutic use given internally, but an important anesthetic property was discovered; in tasting the drug, it was found that a drop on the tongue produced numbness, and experiments proved that agent produced anesthesia of the sensory nerve endings. This benzyl alcohol possessed only slight toxicity. It was found in balsam of Peru and balsam of tolu and was known as phenmethyl-o. The boiling point was found to be very high. It was soluble up to 14 per cent. in water, at room temperature. All the solutions used in the clinic were 0.5 to 4.0 per cent. An anesthetic effect upon the mucous membrane was produced by the drug. Other effects were: (1) sensory nerve paralysis; (2) corneal anesthesia; (3) blocking of nerve fibers, first sensory, then motor; (4) effect on blood pressure (the heart not being affected at all); (5) a slight sedative effect on the central nervous system. The toxicity as compared with cocaine showed that 20 c.c. injected into an animal produced no effect, whereas 20 mg. of cocaine injected would kill an animal. It was tried out in the clinic with marked success. The anesthesia was found to be fully equal to that of cocaine. A bullet was extracted without pain, ingrowing toenails were excised; the crucial tests were in rectal cases, when complete excision of hemorrhoids and excision of rectal fissure were made painlessly. In conclusion it could be stated that phenmethyl-o possessed powerful anesthetic properties and low toxicity, it could be easily sterilized and was very cheap. Dr. Macht said he was especially happy that Providence had enabled him by this discovery to contribute a mite to the alleviation of the sufferings of humanity.

Dr. S. J. MELTZER of New York said that the speaker was to be congratulated upon the findings which he had communicated in his two papers. These papers were to be looked upon from the point of view of practical application, and it was to be hoped that the work would be generally confirmed. In regard to the first paper where it was stated that the papaverine group affected smooth muscle, had Dr. Macht only studied smooth muscle or had he also experimented upon striated muscle? What were the effects upon the central nervous system? Did the papaverine group increase the inhibitory side of the nerve effect, or were the phenomena of the opposite nerves reduced? Perhaps this question was premature and in studying the anal-

gesic effects Dr. Macht would go further and find out more about the drug. He would like to know whether there was merely a local analgesia produced or whether the effect was general.

Dr. T. R. BROWN of Baltimore said that with regard to the clinical aspect, they had been using these drugs and as yet they would not commit themselves as regards the practical value, but it was noticeable that in cases of increased irritability of the gastrointestinal tract, cases associated with diarrhea and mucous colitis, the symptoms were very greatly relieved by the benzyl esters. Benzyl acetate was irritating to the stomach but benzyl benzoate had a distinct use in conditions associated with spasticity of the intestinal canal.

Dr. S. SOLIS COHEN of Philadelphia said that his interest had been excited in Dr. Macht's work. He had found benzyl benzoate of value in treatment of various forms of asthma with dyspnea and in arteriosclerosis with excessively high blood pressure. It was of great use in a particularly irritating cough, known in Philadelphia as "Hog Island Whoop." In cases where one did not care to use morphine, benzyl benzoate was a distinct palliative. Dr. Macht had made a very useful discovery.

Dr. ALFRED H. HESS of New York said that following the use of papaverine for spasm of smooth muscle, he had used it in pylorospasm and the effect of the drug on this condition could be well followed by the x-ray pictures. The normal diameter of the infant's pylorus was 15 mm. By the use of bismuth pills graduated in size, it could be shown that the spasm had relaxed and that the pill had passed the pylorus. Subcutaneous injections of benzyl benzoate had a distinct effect in relaxing the pylorus. The normal pylorus did not seem to be relaxed by the drug, and the pills would pass through whether or not papaverine was used. The remedy was of value in temporary conditions rather than in chronic ones.

Dr. MACHT in conclusion said that he believed that the papaverine group exerted its action peripherally. This was the therapeutic action of all papaveraceæ. Benzyl esters had action on the central nervous system. With very large doses one could get convulsions and respiratory paralyses. The peripheral effect on smooth muscle predominated, however, and he had not found that there was any particular effect on striated muscle. In regard to the toxicity of the benzyl esters, the herbivora apparently could stand a much larger dose and could metabolize it better than carnivora. As much as 20 c.c. per kilo weight could be given to an animal without bad effect. There might be a sedative effect in very large doses. An emulsion of benzyl benzoate had been made which could be easily taken by mouth. In regard to cases where cough was relieved, he could not say whether this was a central effect or not. In pylorospasm it acted better in infants than in adults. It was of use in spastic enuresis in adults and children due to hyperirritation of the bladder or sphincter.

Acute Pancreatitis in Typhoid Fever.—Dr. T. McCRAE of Philadelphia read this paper. The patient had a case of typhoid fever which ran an ordinary course, the temperature being normal on the 24th day. On the 26th day he complained of pain in the upper right quadrant, there was jaundice, and the leucocytes numbered 20,000. Two or three days later the pain subsided and leucocytes dropped to 10,000. Eleven days later there was a definite mass in the region of the gall-bladder, somewhat tender, and a diagnosis of cholecystitis was made. The next day the pain was very severe and bloody stools were passed, blood was present in the urine, and large amounts of blood were vomited. The leucocytes were 26,000. The symptoms subsided for a time when the pain again increased. On the 54th day of the illness operation was performed. It was found that the gall-bladder, duodenum, stomach, and bile ducts were normal. The pancreas was swollen and inflamed. The abdomen was closed and the patient made a good recovery, and in 3 weeks the mass disappeared. On the 82d day he was discharged perfectly well. Points to be observed in this case were that there was very little fever, never complete stoppage of bile, the stools showed no evidence of pancreatic disease. The question then arose—how often was acute pancreatitis mistaken for acute cholecystitis? How often was acute pancreatitis associated with typhoid

fever? The question of hemorrhages was to be considered and this case was presented in order to correct possible errors of diagnosis.

Dr. E. LIBMAN of New York said that this case possessed great interest for him. He had seen the picture in cases in which he had suspected a mild form of pancreatitis. He thought a certain form of pancreatitis occurred in acute infectious disease. It might occur in suppurative conditions after abdominal operations. He believed that diagnosis of acute pancreatitis was not so difficult as it was supposed to be. In making an autopsy on a case of acute hemorrhagic pancreatitis an infiltration on the left side was found. In these cases there was tenderness of the left lumbar region, marked even in patients not sensitive to pain. The relative sensitiveness of the patient to pain was important. It was much more apparent in some patients than others. In acute pancreatitis the pain on the left side could always be elucidated and this was found in no other condition. Another symptom was that in these patients below the ensiform cartilage there was a clear zone and below that again a tympanic note. In cases with a small stone in the ampulla of Vater pain was reflected along the left iliac fossa going to the back, but in none of these cases was there distinct lumbar tenderness on the left side.

Dr. W. TILESTON of New Haven asked if there was any attenuation of amylase in the urine, which was supposed to be a sign of acute pancreatitis.

Dr. MCCRAE, in conclusion, said that there was no tenderness in the left lumbar region in this case. A careful examination was made because when the hematuria appeared it was thought that there was a condition in the kidney producing this symptom.

The Clinical Manifestations of Tropical Sprue.—Dr. E. J. WOOD of Wilmington, N. C., presented this communication. He stated that there had been a great increase in the number of sprue cases in North Carolina, South Carolina, and Georgia. He had seen cases of tropical sprue from the Far East and from Porto Rico as well as in the Southern States: There was only one type in all cases. Sprue was often confused with pellagra, especially by certain English writers. It was no doubt true that many cases of pellagra were complicated by sprue. Sprue needed special attention at this time because it had appeared near many of the Southern cantonments. The symptoms appeared chiefly in the tongue, in the form of small painful erosions. In the diarrhea of sprue the feces were tremendously acid in reaction, yeasty, and passed during the early morning hours. They showed marked loss of fat, as much as 59 per cent. The nitrogen loss was 15 per cent. Functional deficiency of the pancreas was evident in most cases, but not in all. Anemia in sprue was an essential feature. The absence of anemia in pellagra was a distinguishing feature. In sprue the anemia appeared similar to pernicious anemia. Shrinkage of the liver was seen in both conditions. The stomach content changes were fairly similar in both cases and showed a decrease in hydrochloric acid. The beer treatment of Cantley had been found the best.

Major WILLIAM H. WELCH of Baltimore said that in his observations on the control of pellagra by diet he had found buccal lesions and gastrointestinal lesions which might be referable to sprue. He would like to know to what extent pellagra was complicated by sprue. Goldberger's work would seem to show that this was one of the most difficult and perplexing questions. Not a single case of pellagra had been found to develop where diet was properly supplemented. This question of confusion between sprue and pellagra was an interesting and important one.

Dr. E. LIBMAN of New York said that three or four years ago he had seen a case of secondary sprue. He had asked about the loss of knee jerks and absence of hydrochloric acid but had been told that no examination had been made of the stomach contents. In this case Dr. Wood said that examination had been made; was there diminution of acidity?

Dr. A. MCPHEDRAN of Toronto said that a few years ago he had seen a lady, a missionary's wife, who returned from India much affected. Her condition was very grave, with extreme anemia, but there was no material loss of weight. Diarrhea was marked. The tongue had a rather glazed smooth appearance. She

had recurrent attacks of vesicular stomatitis. No treatment produced any effect until she tried the strawberry diet, three or four pounds a day, and she improved on that and for two summers was greatly improved. Two years later she became pregnant and had a marked mitral stenosis. It was believed best to do cesarean section 3 weeks before term. The child was viable. The woman did well for a few days then developed sepsis and died.

Dr. S. SOLIS COHEN of Philadelphia said he had seen a teacher returned from Porto Rico with an undoubted case of sprue. She showed very marked nervous and mental symptoms. He would like to know what was the experience of the members as regards the association of mental symptoms, whether this was a coincidence or not. Looking up the literature on the subject he found that British writers advocated treatment by santonin. This patient received this treatment and recovery followed. Was that the general experience?

Dr. T. R. BROWN of Baltimore said that he had seen two cases from Porto Rico. The stomach contents showed complete achylia. Under treatment the stomach contents returned to normal as regards hydrochloric acid.

Dr. WOOD, in conclusion, said that Dr. Welch had mentioned the work of Goldberger; he was evidently in close touch with the situation. He did not think there had been any work in American preventive medicine more important than this differentiation between the two diseases, unless it were the work of the Rockefeller Institute on uncinariasis. The point to decide was when did sprue begin to complicate pellagra. The pellagra tongue had a different appearance, showing a much deeper red accompanied with profuse and painful salivation. In sprue the tongue was furred and dry because of the absence of salivation. The intake and output of nitrogen had been studied in the two diseases, and in pellagra this was normal. Pellagra was a seasonal disease running from May to August. In sprue the diarrhea, instead of ending, continued; the stools were light colored and more acid. Anemia was not associated with pellagra. Anemia in sprue was essential for diagnosis. In answer to Dr. Libman, there was an absolute absence of hydrochloric acid in sprue. In regard to the nervous disturbances mentioned by Dr. Cohen, these were marked in pellagra and perhaps the case mentioned was really one of pellagra and not sprue. Dr. McPhedran referred to the strawberry diet; that had not been found of any service. Santonin and emetine had been discarded as worthless. No treatment except dietetic control and rest for a prolonged period had been found of any avail. He had a patient with sprue, a New Hampshire man who had never been South. When the man came in he was supposed to have carcinoma of the stomach, but it was found that he had a case of typical sprue. The patient survived three years. He had lived in New Hampshire and Boston all his life.

Further Observations on the Bacteria of the Intestinal Tract.—Dr. W. W. FORD of Baltimore made this presentation. The Gram positive bacteria found in dejecta were found to be aerobic forms due to ingestion of milk, water, etc., and occurred in foods upon which children were nourished. A study was made to find out if these large Gram positive organisms could be anaerobic. The stomach and portions of the intestinal tract of calves were studied. Large Gram positive organisms were obtained from every part of the intestinal canal. It was the same in Princeton or Baltimore, the Gram positive spore bearing bacteria were found normal to the intestinal canal. Anaerobic cultures were always negative, the organisms were always aerobic. Differences were found in organisms grown in intestinal juices and those grown on artificial media. A search was made to see if encapsulated bacteria could be found in the dejecta and by a new method of staining by carbol fuchsin (which proved a valuable contribution to bacterial technique) it could be determined whether there were capsulated bacteria in the intestine or not. It was proved that there were no encapsulated forms present above the ileocecal valve. Below this valve there were present Gram positive organisms encapsulated, of the morphology of the gas bacillus. Aerobes were found above the valve, anaerobes below the valve. The general applicability of these facts to man was then con-

sidered. In Baltimore milk there were present spore-forming gas bacilli. In the neutralized whey were found hemolytic substances, due to bacteria. These were toxic for rabbits and guinea pigs in subcutaneous inoculation. If the whey were filtered, the filtrate was also toxic. It was found that milk cultures of the gas bacillus were always poisonous to animals. Work was now being done to determine whether this organism was vegetative in the intestinal tract. It would then be possible to determine whether this bore any relation to the question of the production of scurvy by the feeding of children with pasteurized milk.

Dr. W. H. WELCH of Baltimore said he would like to know whether toxin had been demonstrated in the milk and if so whether the carbohydrate content of the milk had been reduced. Gould had used the minimal amount of carbohydrate and had examined the toxin after 24 hours. The reason the toxin was overlooked was that if the carbohydrate were not changed the acid formed was destructive to the toxin. Eighteen hours was too early to look for the toxin. Search for the toxin could be made after the reduction of lactose. Dr. Flexner had received a letter informing him that the British had taken 100 tetanus horses and were immunizing them against the gas bacillus toxin, in order to have an antitoxin against tetanus and the gas bacillus. They could thus control tetanus and gas gangrene at the same time. It was hoped that a trivalent serum could be obtained against tetanus, gas gangrene, and trench fever. All infection could be controlled by a single dose.

Major S. FLEXNER of New York said that the factor influencing the degree of toxicity of the cultures which Dr. Ford had described was the control of the carbohydrate. There were at present unknown differences in the toxin producing powers of the various strains of the Welch bacillus, these were similar to conditions relating to the diphtheria bacillus. He believed that the New York acid diphtheria bacillus strain No. 8 was in use all over the world. It was known to produce very active toxin. This was true also of the Welch bacillus. Dr. Bull found one strain which was superior to the others in antitoxin producing power. It surpassed the English strain No. 617 in this respect. In regard to milk cultures, the toxin producing power should be determined not only in milk but in other media. There were thus two factors, the carbohydrate control and the toxic power, to the latter of which there was an almost infinite degree of gradation.

Dr. S. J. MELTZER of New York said that he was interested to hear Dr. Ford say that there was spore formation of the gas bacillus. Was any attention paid to the tetanus bacillus, whether it had spore formation?

Dr. FORD, in conclusion, said that he had tried two methods of increasing the toxicity of the milk cultures: (1) he had tried to get milk whey in which lactose was taken away, but the gas bacillus did not multiply well in milk of that character; (2) the acidity of the milk was then neutralized by the addition of powdered chalk and it was found that the filtrate from such milk cultures had more marked toxicity. Dr. Flexner had brought up an interesting point. In the study of pasteurized milk they had been forced to limit their observations to study of such organisms as might be obtained from this source. The gas bacillus obtained from soil and other sources would be more poisonous than that from milk. The variation of toxicity in strains was marked. The first culture obtained had a high toxicity which gradually diminished as the result of repeated passage. They never got such a good strain again. The toxic production by the gas bacillus in other media than milk had not been determined. It was premature as yet to attempt to answer the question as to whether pasteurized milk ever would develop poisonous properties. In the majority of cases the gas bacillus existed in the intestinal tract in spore form but observations so far did not indicate that there was any vegetation there. Probably the same thing would hold good for the tetanus bacillus.

The Tension of the Gases in the Afluent and Effluent Blood of the Lungs.—Dr. R. G. PEARCE of Cleveland, O., presented this paper. The writer stated that the method of determination of tension of gases was

the most rational and direct method for testing the functional capacity of the heart and lungs. It had been used for determining the amount of improvement in the lungs after gas attacks. The amount of the work of the lungs with that of metabolism was correlated. In passing through the lungs the blood lost a percentage of oxygen and by increase of metabolism there was also increase of oxygen and more carbon dioxide than usual. Thus the determination of the carbon dioxide tension as the blood entered and left the lungs would give a very good indication of the ability of the circulation to cope with the needs of the body's metabolism. In order to find this the percentage of the carbon dioxide in the alveolar air at a certain level of metabolism was determined. With moderate exercise it was found that there was parallelism between the oxygen metabolism of the effluent and the affluent blood. With superventilation or hyperpnea there was a marked decrease in carbon dioxide tension. The method was applicable to cases where it was necessary to determine the respiratory capacity in respect to metabolism. In soldiers who had been gassed there was a considerable impairment of the respiratory capacity.

Dr. C. F. HOOVER of Saffordville, Kan., said he had seen a man working at the Panama Canal seized with a sudden attack of air hunger, when climbing a small slope. The paroxysm came without warning. In experiments with this patient later it was found that raising the body from the floor by straightening the arms would at once cause a marked attack. The radial pulse disappeared, the other pulses remaining normal. There was a brachial rigidity but the blood pressure on the leg was not affected. In that man there was superventilation beyond the demands of the gaseous metabolism. In this case there was a history of hemoptysis several years ago. There was a slight lesion in the apex of the lung, but no enlargement of the heart. Evidently the condition was a tuberculous mediastinitis. Dr. Pearce's metabolic study showed the reason for the unusual condition of the lung ventilation and offered proof of peripheral control of ventilation through the peripheral nerve supply.

The Respiratory Significance of Moisture in the Air Spaces of the Lungs.—Dr. C. F. HOOVER also read this paper. In the study of gassed men in France it was seen that large quantities of foam issued from the nose and mouth while there were cyanosis and air hunger. There was a disparity between these two symptoms. In ordinary cases cyanosis would appear before air hunger. Introduction of oxygen, while it relieved cyanosis did not alleviate the air hunger. The men would not tolerate the oxygen mask over the face. They felt more comfortable breathing atmospheric air. The reason of this was that the respiratory spaces were all full of foam. In some bronchioles there was CO_2 and in some the oxygen was minus. Thus giving oxygen might not get rid of the CO_2 . This was similar to pneumonia where the consolidated lung was contributing unrespired blood. Unless the CO_2 was removed, giving the oxygen caused no effect. When the CO_2 pressure in the blood was removed, oxygen could be given with relief of symptoms.

Dr. S. J. MELTZER of New York said he had read an article on the use of oxygen in pneumonia; he had used a different method. He had no experience of cases in which there was fluid in the trachea or bronchi, but in regard to pneumonia and cardiac disease the method he had used for administration of oxygen had immediate effect in removing the cyanosis, and the subjective symptoms were relieved, even in cases where the patient afterward died of heart disease. The mask was not a comfortable one. It really absorbed the quantity of carbon dioxide which the patient spontaneously released. The method of choice by means of a depressor on the tongue would drive out mechanically through the nose all the excess of carbon dioxide.

Dr. A. MCPHERAN of Toronto asked if oxygen was given subcutaneously to produce the effect.

Dr. HOOVER said that when a man had consolidation of the right lower lobe in pneumonia and no other sign of involvement, and oxygen was given, the cyanosis disappearing, it was a very difficult problem to say why one had got rid of the cyanosis. Cyanosis was due to unoxidized blood in the aortic stream and that would not be touched by giving of oxygen. Regarding

the subcutaneous or intravenous use of oxygen, one would be so little apt to use this method that it could be considered negligible. The problem was why did the cyanosis disappear and not the air hunger, and this was only to be explained on the basis of unoxidized blood.

The Practical Value of Diphtheria Toxin-Antitoxin Injections in Immunization, as Determined After a Test of Three Years.—Dr. WILLIAM H. PARK of New York read this paper. Evidence, he said, was accumulating each year as to how long the immunity would last after toxin-antitoxin injections; also evidence as to the harmlessness of the procedure—two features which constituted the value of the immunization. Young infants under six months of age were protected by immunity inherited from the mothers. After this age the inherited immunity rapidly decreased and at 2 years of age children were least protected and consequently the greatest number of deaths occurred at that age. At ten years of age the mortality was one thirtieth that in the second year. In regard to the harmlessness of the injection, careful study had shown that earlier procedures were lacking in sufficient care. The meat in which the diphtheria bacillus was planted was allowed to ferment. Lately a whole broth was made, heated, and no fermentation took place. Some 10,000 cases of immunization had been done and no death had occurred. Four cases of collapse had happened in that number. Within the last six months there had been no untoward results. Twenty per cent. of children had shown a slight rise of temperature. From one to three units could be given with perfect safety. In regard to the duration of immunity it would seem as if artificial immunity in 80 per cent. of cases would be as permanent as natural immunity. It had not dropped off more than 2 per cent. in two years. If it should be lost the child could be immunized again with equal effectiveness. The immunity at birth was found in 80 per cent. of children. It dropped to 60 per cent. in the second year. Non-immune mothers had non-immune children. Immune mothers always had immune children. In regard to frequent testing for immunity it was easier now to give a toxin-antitoxin injection than to perform the Schick test every three months.

Dr. A. F. HESS of New York said that at the Hebrew Asylum the children giving a positive Schick test were immunized by toxin-antitoxin injection. There had been no cases of diphtheria in the institution in the last two years. At first all cases giving a positive Schick test were immunized, but babies were found to be immune at first and then lose their immunity; thus it would seem best to immunize all individuals during the first six months of life in order to render the institution free of diphtheria. Untoward reactions had been occasionally noted in children of 3 or 4 years, thus one child had an immediate collapse with fever, vomiting, and diarrhea. Recent procedures had been found very harmless, however, and it could be said that as complete an immunity could be obtained in the case of diphtheria as had been done by smallpox vaccination. Dr. Park felt now that all the protein reactions could be avoided and the technique made entirely harmless.

Transplantation of Tuberculous Lymph Nodes.—Dr. C. T. RYDER of Colorado read this paper, in which a new experimental method was outlined. The experiment was the transplantation of infected tissue of diseased animals into healthy tissues of normal animals. Tuberculous lymph nodes were used. Guinea pigs were infected with small doses of virulent human bacilli and when the lymph nodes became markedly enlarged they were transplanted under the abdominal skin of healthy animals. When these animals' inguinal nodes became enlarged they were transplanted into a third series of animals and so on. The skin was found to heal in two weeks, the gland remaining in place without inflammation; the first week it acted as a free foreign body and if the node sloughed out the host escaped infection. The second week adhesions took place and blood vessels from the host's tissue began to penetrate the implanted node. In three to five weeks the host's inguinal nodes enlarged and ulceration took place and within two to four weeks there was generalized tuberculosis. The tuberculin reaction remained negative. If a second node were implanted the ulcer would open, discharge, and heal, but the first ulcer never healed.

With other tissue, such as spleen and liver, the results were essentially the same. The complete experiment would, of course, be the transplantation of the entire tuberculous organ, but as yet the technique had not been mastered.

Immunity in Cancer.—Dr. F. C. WOOD of New York read this paper. He said there was no branch of medical investigation which had suffered so much from lack of accurate thinking and correct nomenclature as the cancer problem. These facts had caused a great deal of work which need not have been done had the exact conditions been appreciated. Connected with the idea of immunity in cancer were four different phenomena. Spontaneous disappearance of primary tumors might occur, sometimes following no interference, sometimes following infection, sometimes after partial removal by operation; this had been considered due to immunity. There was, however, no evidence that this was immunity. Disappearance of primary tumor often coincided with growth of metastases. The so-called organ immunity was not real, because if tumors were implanted in the spleen they would grow as well there as elsewhere. The fact that metastases did not take place in the spleen was because of vascular conditions. Disappearance of tumors in animals was very infrequent. The failure to implant a tumor in an animal and its resistance to a second implantation had been considered immunity, but in these cases a second tumor might appear and grow. These errors had arisen from transferring the nomenclature of bacteriology to the question of tumors. Cellular extracts, filtrates, etc., had been prepared and colloidal material and lecithins used to produce immunity. None of these preparations influenced the growth of an already established tumor. The tumor could not be considered separable from the host, but was identical with the host's normal structures. The idea of stimulation of the body against the tumor had been held and autoagglutinins had been produced. These were different, however, from cytolytic antibodies. Lymphocytosis had not been found to have any influence upon the growth of tumors and it had to be stated that the problem of immunizing the body against a tumor had still to be worked out.

Studies of Chronic Myocarditis.—Dr. H. A. CHRISTIAN of Boston made this presentation. In the recent studies of the heart by means of the electrocardiograph there had been a tendency to emphasize the importance of the valve lesion rather than myocardial function. Most cases of myocardial insufficiency were called mitral insufficiency. The thickened valve was not differentiated from that with the orifices enlarged. The pathologist would term such cases myocarditis as had demonstrable lesions at autopsy, whereas the physician used the word to mean myocardial insufficiency. Cabot some years ago had found that only 22 per cent. of the diagnoses of chronic myocarditis made during life were found correct at autopsy. Dr. Christian said his experience was different and he thought fewer mistakes were made in this diagnosis than in others. The pathologist and the physician, however, were talking of different things and the terms did not correlate. The autopsy would not show any sign of the interstitial type of myocarditis. Mitral insufficiency was a rare lesion when considered as autopsy material. In analyzing the cases Dr. Christian found that there was a great frequency above forty-one years. In 407 cases, 112 gave a history of rheumatism, 35 had a positive Wassermann, 110 were chronic users of alcohol, 178 had high blood pressure; one-half the cases had chronic nephritis. Overeating was difficult to estimate as a cause, but 118 persons were overweight. In conclusion, it could be said that the condition was a very common one; the change was primarily in the heart muscle. The cause could not be determined. At autopsy a large percentage showed no changes in the coronary valves and no enlargement.

Dr. E. LIBMAN of New York said that it was an important matter that the disease of the myocardium should be studied. Dr. Christian had made a very appropriate study. Dr. Libman disagreed on the question of terminology. He did not like to use the term myocarditis interchangeably with the term myocardial insufficiency. He believed that one should try to find a cause for the myocardial insufficiency. If there was a history of rheumatism there might be a true myocardial lesion, but with syphilis the disease would be arterial.

With diffuse arteriosclerosis of the coronary system there must be muscular lesions to get myocardial insufficiency. One should see if the patient was anemic. Transfusion had often removed the cause of myocardial insufficiency. Bleeding fibromata, thyroid disease, might be the underlying cause of myocardial insufficiency. In myocarditis there were definite electrographic changes shown. It would be more correct to speak of mitral insufficiency than to speak of myocardial disease. Dr. Libman said that he could speak from personal experience upon the probability of focal infection causing myocardial symptoms. He had suffered from an infection of the sphenoidal sinus accompanied by definite myocardial distress.

Dr. S. S. COHEN of Philadelphia said that he wished to remark upon the nomenclature. Da Costa used to call these cases dilated heart. Where there was actual myocarditis he called it fibroid heart. Dr. Cohen said he preferred to speak of "myopathics" and not commit himself as to whether there was definite myocarditis or not.

Dr. H. S. PLUMMER of Rochester, Minn., said that one must consider if there were damage to the heart by overloading, either by high blood pressure or hyperthyroidism. The latter was a very common cause of myocardial insufficiency. It had been recognized that one-third of the cases were due to adenomata of the thyroid. These probably originated in fetal rests. They were different from the condition of Graves' disease. The adenomatous tissue developed postnatally and was erratic in development, so that all degrees of thyroidism were obtained without regard to the thyroid demands of the tissues. This condition was constantly overlooked by the best men. These patients ran a metabolism 30 to 50 per cent. above normal, and this would drop to normal with the removal of the adenoma. The abdomen might be full of fluid and yet be perfectly normal within three weeks after the excision of the adenoma. Blood pressure in these cases was due to increased minute volume flow through the right heart.

Dr. S. J. MELTZER of New York asked what Dr. Christian thought about nicotine; did he consider that was among the causative factors? Sixteen years ago a man had come to him with a cardiac condition. He told him he had extra systoles and advised him to stop smoking and face the music. The man then went to Osler, who told him "neurasthenia," which was no doubt also true. The man died of angina pectoris and pulmonary edema. He was not willing to stop smoking and face the music.

Dr. A. STENGEL of Philadelphia said he thought myocardial insufficiency and myocarditis were two different things. A patient dying from aconite poisoning was not dying from myocardial disease, but was surely dying of myocardial insufficiency. In hyperthyroidism the patient was suffering from myocardial poisoning, but not necessarily from myocardial disease. The diagnosis of acute myocardial disease was exceedingly difficult to make. In the absence of evidence of valvular disease one was justified in saying myocardial disease, but many of these cases cleared up when some focus of infection was removed and it was proven that the myocardial symptoms were but a manifestation of the toxemia. Myocardial insufficiency should be separated from myocardial disease. The latter called for treatment directed to the circulation itself and removal of the cause of toxemia. It was almost impossible to determine at the bedside whether the patient had myocardial disease or simply myocardial weakness. The weakness was due to depression of the sensory motor mechanism rather than disease of the muscle itself.

Dr. H. A. CHRISTIAN, in closing, said that he did not care what the condition was called so long as the doctors defined their terms. There were as many objections to the terms offered on the floor as to the word myocarditis. They went from the frying pan into the fire. In the cases studied the chief lesion was cardiac. All were advanced cases. Most of the patients were dead. They were not cases of anemia or of thyroid disease; the cases did not occur in a goiter belt and there was no evidence of thyroid hyperactivity. Most of the patients had normal electrocardiograms. Nicotine could not have played an essential part as there were as many women as men among the patients. Therapy gave only temporary effect; they all reacted well to digitalis.

The Etiology and Pathology of Rocky Mountain Spotted Fever.—Dr. S. B. WOLBACH of Boston read this paper. This disease was characterized by diffuse hemorrhages and necroses of the skin, fingers, toes, and genitalia. It was transmitted by the tick (*Dermacentor anisoma*) and was prevalent in Oregon, Idaho, Wyoming, and California, and was spreading eastward to Montana. It was a disease of the peripheral blood vessels, caused by a minute parasite, in the form of small bipolar bodies. The reaction of the body was by proliferation of large multinuclear phagocytic cells. The organism was found distributed in the smooth muscle fibers. The disease could be duplicated with great accuracy in susceptible animals. Microscopical studies showed that the organism was paired, lanceolate, and surrounded by a halo. In infected animals the tissues became flooded with the organism. At present the organism had not been successfully cultivated. It had very little resistance to heat and drying. In its selection of tissues it was extremely specific.

Dr. WILLIAM H. PARK of New York asked if the doctor had been unable to get any cultivation.

Dr. S. B. WOLBACH said he had tried spirochete media and protozoa media, but comparing it with other organisms it was found to survive less in defibrinated blood and citrated blood than did spirochetes or trypanosomes.

(To be continued.)

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

NEW YORK STATE BOARD OF MEDICAL EXAMINERS.

January, 1918.

(Continued from page 926.)

CHEMISTRY.

1. Discuss the digestive action of pancreatic juice.
2. On what theory is dialyzed iron used in arsenic poisoning?
3. Name the halogens in their order as to chemical affinity. What are the general characteristics of the halogens?
4. Describe a test showing the presence of strychnine in the stomach contents.
5. Discuss urea, giving its formation in the body, and a method used for its detection.
6. Discuss the significance of increased phosphates in the urine.
7. What chemistry is involved in the coagulation of the blood?
8. What is sugar of lead? How is it manufactured synthetically?
9. Give the chemical composition of lecithin. Where in the body is lecithin found?
10. Distinguish between saccharin and glucose.
11. Describe the chemical changes taking place in fats during starvation.
12. After air has been breathed several times, what chemical changes take place in it that make it unfit for breathing?

PATHOLOGY.

1. Give the blood findings in myelogenous leucemia.
2. Describe briefly the lesions resulting from chronic phosphorus poisoning.
3. Describe fatty degeneration of the heart muscle.
4. Describe acute suppurative arteritis.
5. Describe tuberculous adenoma.
6. Describe the gross anatomy of hard chancre.

BACTERIOLOGY.

7. What are the most common organisms found in septic endocarditis? How would you make a bacteriologic diagnosis of this condition during life?
8. Describe the tetanus bacillus. What kind of injury favors the development of tetanus and what prophylactic measure should be employed?
9. Given a pure culture of tubercle bacillus, on what media would you grow it? Describe one variety of tuberculin.

10. What is meant by prophylactic typhoid vaccination? What substances are used for this purpose?
11. How may tetanus antitoxin be administered with hope of success in a patient already having the symptoms of tetanus?
12. Describe in detail how you would examine spinal fluid for meningococci, morphologically and culturally.

DIAGNOSIS.

1. What is the jugular venous murmur? What is its diagnostic significance?
2. At what period after infection do the secondary skin symptoms of syphilis appear and what is their chief characteristic?
3. Describe eczema and give its diagnosis.
4. What is meant by the term "girdle pains"? When persistent of what is it significant?
5. By what sign is one able to localize the site of a lesion involving a facial nerve and causing a simple, uncomplicated facial palsy?
6. Describe the symptoms and the clinical course of suppurative phlegmon of the tonsil.
7. What are the symptoms of inflammation of the frontal sinus?
8. State the symptoms suggestive of the presence of a mediastinal tumor. Differentiate it from tuberculosis, empyema and aneurism.
9. Name five common conditions occurring between the pylorus and the ileocecal valve that are attended by hemorrhage into the cavity of the bowel.
10. Differentiate between a tumor in the right abdomen due to a distended gall bladder and that due to a hydronephrotic kidney.
11. Differentiate between a renal calculus impacted in the right ureter and chronic appendicitis.
12. In what respect does the onset of edema due to renal diseases differ from that of edema due to cardiac disease?

ANSWERS.

CHEMISTRY.

1. The *digestive action of the pancreatic juice* is due to its enzymes. *Amylopsin*, an amylolytic enzyme, hydrolyzes undigested starch or dextrin to maltose, and later on this is converted into glucose, fructose, and galactose. *Trypsin*, a proteolytic enzyme, hydrolyzes protein to amino-acids, at the same time yielding proteoses, peptones, and polypeptides. *Steapsin*, or pancreatic lipase, converts the fats into glycerol and fatty acids.
2. *Dialyzed iron* is used in *arsenic poisoning* because the ferric hydroxide changes the arsenic into ferrous arsenate which is insoluble and therefore harmless.
3. The *halogens, in order of their chemical affinity*, are: Fluorine, chlorine, bromine, and iodine.
The *general characteristics of the halogens*: They are all univalent, they form hydrides (which are colorless gases, soluble in water), they are irritant, they have bleaching and disinfectant properties, they combine directly with most metals to form binary compounds (chlorides, bromides, etc.).
4. *Tests for Strychnine*.—If a piece of potassium dichromate is drawn through a solution of strychnine in sulphuric acid it is followed by a streak of color; at first blue, quickly followed by violet, rose-pink, and yellow.
5. Urea, CON_2H_4 , is found in the urine, blood, lymph, perspiration, bile, liver, spleen, brain, and elsewhere in the body. It is a colorless, odorless, crystalline substance, basic in character, neutral in reaction, soluble in one part of water. It is isomeric with ammonium isocyanate. In the body urea is the end product of protein metabolism, and is the form in which nitrogen is eliminated.
The greater part of the urea produced in the body is formed in the liver. The liver cells form the urea from two sources: (1) The larger amount, produced by the liver cells, is derived from the amino-acids which have been absorbed from the small intestine, and which are not required by the tissues; this constitutes the *exogenous urea*. (2) The smaller amount, produced by the liver cells, is derived from the ammonium carbonate, which is the outcome of nitrogenous catabolism, and which is derived from the tissues; some is also

produced by the action of the uricolytic enzyme upon uric acid; this constitutes the *endogenous urea*.

The amount of *urea* eliminated in the urine depends largely upon the amount of nitrogen contained in the food, and also upon the extent of protein metabolism going on in the body. It is increased in fevers, in diabetes, pneumonia (during resolution); it is decreased in diseases of the liver.

The presence of urea can be shown by allowing a few drops of the fluid to partially evaporate on a slide, and adding a drop of pure nitric acid; crystals of urea nitrate will be formed and can be recognized under the microscope.

6. *Increased phosphates in the urine may indicate*: Rich diet, particularly animal food or vegetable food which contains cereals rich in phosphates; increased mental activity; excessive metabolism; convalescence from acute diseases; acute mental and nervous diseases; leukemia; and phosphatic diabetes.

7. "As to the nature of the chemical changes involved in coagulation, opinions differ. It is universally admitted that the corpuscles, particularly the leucocytes and plaques, contain a zymogen, *prothrombin*, from which an enzyme, *thrombin*, is produced. It is also generally, though not universally, conceded that this enzyme causes coagulation by splitting fibrinogen into the insoluble fibrin and the soluble fibrinoglobulin; and that the continued existence of the enzyme in the circulating blood causes death by thrombosis. The presence of calcium salts is necessary to coagulation, as is shown by the prevention of such action by the removal of calcium by oxalates or other precipitants of that metal, and by the fact that oxalate plasma regains its power of coagulation on restoration of calcium salts. As the separated fibrin contains a considerable amount of calcium, it has been suggested that during coagulation the calcium-containing thrombin gives up its calcium to fibrinogen, with the formation of fibrin, while prothrombin, which has a less calcium-content than thrombin, is regenerated, and may in turn regenerate thrombin by combination with calcium salts (Peckel-haring). According to another explanation of the chemism of the process the leucocoeleuin, or nucleic acid of the nucleohiston of the leucocytes, in the presence of calcium salts, decomposes fibrinogen with formation of an albumose-like substance (fibrinoglobulin) and a hypothetical substance, called *thrombosin*, which latter, combining with calcium, forms fibrin (Lillienfeld). This latter view, so far as concerns the activity of nucleohiston in the process, is supported by the fact that solutions of fibrinogen, not spontaneously coagulable, are coagulated on addition, not only of blood-serum, but also of cells, such as yeast, spermatozoa, etc., containing nucleoproteids. These views may be reconciled, with the exception of the supposed existence of thrombosin, upon the supposition that prothrombin and nucleohiston are identical either in kind or in action."—(Witthaus' *Manual of Chemistry*.)

8. *Sugar of lead* is lead acetate. $\text{Pb}(\text{C}_2\text{H}_3\text{O}_2)_2$. It is formed by dissolving lead monoxide in acetic acid and heating:

9. *Lecithin* is a phosphorized fat, containing one atom of phosphorus and one atom of nitrogen. It is probably a derivative of glycerophosphoric acid. The formula has been given as $\text{C}_{44}\text{H}_{88}\text{NPO}_8 + \text{H}_2\text{O}$, but the lecithins are a group of substances with varying composition. Lecithin is found in the brain, nerves, blood, milk, bile, and seminal fluid.

10. *Saccharin* occurs in white crystals or as a white crystalline powder; it is intensely sweet, about 500 times sweeter than sugar; is sparingly soluble in water, about 1 part in 290 of water; on being heated with Fehling's solution it does not deposit cuprous oxide; it does not ferment with yeast.

Glucose occurs as a thick, syrupy liquid, with a sweet taste; it is very soluble in water; on being heated with Fehling's solution a copious red precipitate of cuprous oxide is produced; it ferments if yeast is added to a solution, alcohol and carbon dioxide being formed.

11. Ordinarily the fats are split up into fatty acids and glycerin; the fatty acids are split up into simpler and lower fatty acids, and finally reach the stage of CO_2 and H_2O . During starvation intermediate acids are produced, *e. g.* beta-hydroxybutyric acid; this latter

is oxidized into aceto-acetic acid, and from this acetone is produced the removal of CO_2 . The beta-hydroxy-butyric acid and aceto-acetic acid are found in the blood, and the aceto-acetic acid and acetone are excreted in the urine.

12. After air has been breathed several times, the following chemical changes take place in it and make it unfit for breathing: The oxygen is diminished; the carbon dioxide is increased; small quantities of marsh gas, ammonia, and hydrogen are often present; it has been asserted (and also denied) that small amounts of organic matter and fatigue-toxins are also present.

PATHOLOGY.

1. In *myelogenous leucemia*, the blood shows: An enormous leucocytosis, the presence of myelocytes, increase in mast cells, diminution in the number of red corpuscles, the presence of nucleated red corpuscles, low color index, increase of number of blood plates.

2. *Chronic phosphorus poisoning* presents the following lesions: Periostitis and necrosis of the jaw (generally the lower jaw), followed by sequestrum formation and suppuration; the neighboring tissues may be involved, as well as the bone. In severe or neglected cases both jaws may become involved. General fragility of the bones has been observed.

3. *Fatty degeneration of the heart muscle*. "This consists in the transformation of portions of the muscle fibres of the heart into fat or closely allied substances, which collect in the fibres in larger and smaller droplets, sometimes few in number, sometimes so abundant as almost entirely to replace or conceal the normal striations. This degeneration is sometimes quite universal, but is more apt to occur in patches, giving the heart muscle a mottled appearance. This mottling may usually be best seen on the papillary muscles. The degenerated areas have a pale yellowish color, and the muscle tissue is soft and flabby; but when moderate or slight in degree the gross appearance may be little changed, and the microscopical examination be necessary for its determination. This degeneration may lead to thinning of the walls, or to rupture of the heart, or to inability to fulfil its functions. It is not infrequently the cause of sudden death." (Delafield and Prudden's *Pathology*.)

4. *Acute suppurative arteritis* "occurs in the arteries traversing areas of suppurative inflammation, and results from the extension of the suppurative process. It may also occur in consequence of the lodgement of infected emboli or as a result of infection of thrombi within the vessels. When the process extends from without, the adventitia and then the media are infiltrated with round cells, and in cases of some of the larger vessels there may be visible points or collections of pus. The process may extend as deeply as the intima, and may completely perforate the wall of the vessel, leading to hemorrhage. The intima itself is not directly involved by the suppurative process from the lack of independent blood supply, but the emigrated leucocytes may infiltrate it, and degenerative changes are common in the endothelium. Where the process begins by infection within, as through softened thrombi or infectious emboli there is first necrotic or degenerative destruction of the intima, and subsequently infiltration of the media and adventitia with emigrated round cells." (Stengel's *Pathology*.)

5. "*Tubular adenoma* is very common in mucous membranes possessing tubular glands. Tubular adenomata are usually soft, slightly translucent, and somewhat vascular. The tubes are lined with cylindric cell epithelium. On section, when cut transversely, the tubes appear as circles possessing central lumina and borders of regular cylindric epithelial cells. When cut longitudinally, they often show lateral buds or even bifurcations, the surface ends of the irregular tubules open on the mucous membrane; at the other end they terminate in blind sacs extending to varying depths; the tubes may be so closely packed together as to show but little fibrous stroma; the cylindric cells lining the tubes are usually two or three times as long as normal. This variety of adenoma is prone to undergo malignant transformation, many of the cancers of the rectum and uterus arising from this tumor." (Coplin's *Pathology*.)

6. *Hard chancre*. "At the point of inoculation in a few weeks a focus of inflammation develops—the ini-

tial sclerosis. This may be in the form of a papule or a vesicle, and in either case erosion of the surface is apt to occur and a hardening of the deeper tissues leading to the so-called chancre. In this primary lesion, in addition to more or less fluid and cellular exudate, there may be obliterating endarteritis, a small spheroidal-cell infiltration of the connective tissue cells, especially near the blood-vessels, swelling of the vascular endothelium, and an occasional development of giant cells. This new tissue may become fibrous and the initial lesion heal. Usually in connection with, or following the development of, the initial lesion there is a hyperplasia of the lymph-nodes belonging to the anatomical district of the lesion. These become hard and swollen. These hyperplastic lymph-nodes, called buboes, are not apt to suppurate except as the result of concurrent infection with pyogenic bacteria, but the swelling gradually subsides." (Delafield and Prudden's *Pathology*.)

BACTERIOLOGY.

7. *The most common organisms found in septic endocarditis*, are: *Staphylococcus pyogenes*, *streptococcus pyogenes*, *streptococcus viridans*, *pneumococcus*, *gonococcus*, the bacillus of influenza, *treponema pallidum*, *bacillus typhosus*, *tubercle bacillus*, *bacillus of anthrax* and *colon bacillus*.

The *bacteriological diagnosis* is made, during life by isolation and culture of the bacteria from the blood. The most exact antiseptic and aseptic precautions are necessary; the blood is obtained in a small sterile syringe, from one of the median basilic or internal saphenous veins. Cultures are then made on glucose-meat-infusion agar or broth.

8. *The bacillus of tetanus* is a small, slender rod with rounded ends, and characterized by its peculiar spore formed at one end of the bacillus and giving it the appearance of a pin; it is purely anaërobic, and cannot be developed at all in the presence of oxygen. It is from 2 to 4 mikrons long and from $\frac{1}{4}$ to $\frac{1}{2}$ mikron in breadth; it is slightly motile, and stains with the ordinary anilin dyes and by Gram's method. It generally comes from the soil, and is found in penetrating wounds. It appears in two forms, the spore-bearing form, as described above, and the vegetative form, which is a short bacillus with rounded ends, and which may occur singly or in pairs, or may form long filaments. It grows in gelatin stab cultures in the middle of the medium and the colonies look something like a fir tree; its growth is slow, and a disagreeable odor is at the same time emitted. In bouillon, it grows near the bottom of the tube and produces gases.

Deep, punctured or lacerated wounds, in which there has been loss of tissue, or in which dirt or splinters have become imbedded; also gunshot wounds and compound fractures, are the injuries which favor the development of tetanus.

Prophylaxis consists in thorough purification of all wounds which have been exposed to infection by dirt, and all wounds of the kind just mentioned. Injections of anti-tetanic serum into the muscles of the gluteal region are of value. See question 11.

9. A pure culture of tubercle bacilli may be grown on glycerin bouillon, glycerin potato, or blood serum.

Koch's old tuberculin "is produced in the following manner: Tubercle bacilli are grown in slightly alkaline 5 per cent. glycerin-pepton bouillon for six to eight weeks. At the end of this time, growth ceases and the corrugated pellicle of tubercle bacilli, which during growth has floated on the surface, begins, here and there, to sink to the bottom. The entire culture is then heated on a water-bath at about 80°C . until reduced to one-tenth of its original volume. It is then filtered either through sterile filter paper or through porcelain filters. The resulting filtrate is a rich brown, syrupy fluid, containing the elements of the original culture medium and a 50 per cent. glycerin extract of the tubercle bacilli. While the glycerin is of sufficient concentration to preserve it indefinitely, 0.5 per cent phenol may be added as an additional precaution. Dilutions of this fluid are used for diagnostic and therapeutic purposes." (Hiss and Zinsser's *Bacteriology*.)

10. *Prophylactic typhoid vaccination* is a form of active immunization against typhoid fever by injecting emulsions of dead or attenuated typhoid bacilli.

Substances used for this purpose are: Killed cultures of the typhoid bacillus, bacterial extracts and preparations, living cultures of the typhoid bacillus, sensitized cultures of the typhoid bacillus.

11. In a patient already having the symptoms of tetanus, the antitoxin may be administered:—(1) Intravenously, 10,000 to 20,000 units of antitoxin at once, and repeat the dose if no effect is apparent or if the good effect wears off, in about 18 to 24 hours. After one or two intravenous injections the good effect may be maintained by direct intramuscular injections of from 5,000 to 10,000 units for one or two doses. (2) From 3000 to 5000 units should be given intraspinally by means of lumbar puncture. This dose should be repeated every 24 hours unless the symptoms have markedly ameliorated. A quantity of cerebrospinal fluid should be removed before the serum is injected. (3) If a surgeon is at hand, from 500 to 1000 units of antitoxin should be injected slowly intravenously into the sheaths of the nerve-trunks leading from the infected region. These injections are directed to be made as near the trunk as possible, and to distend the nerve so as partly to neutralize and partly mechanically to interrupt the passage of toxin to the cord or brain. Both the intraspinal and the intraneural injections are given under light chloroform anesthesia. (From Kolmer's *Infection, Immunity and Specific Therapy*.)

12. "The patient should lie on the side, with the back bent forward as far as possible, in order to separate the vertebræ and make the lumbar region prominent. The sitting posture may also be assumed with the back bent forward. A local anesthetic is usually all that is necessary. Very often the patient is comatose and requires none. A long, strong aspirating needle is introduced midway between the second and third or third and fourth lumbar vertebræ, either straight in from the mid-line of the back or about an inch to the side and directed a trifle inward. It should be inserted from 2 to 3 cm. in a child and from 7 to 8 cm. in the adult. As soon as the subarachnoid space is entered the fluid makes its appearance, usually drop by drop; but when large in amount and under pressure, in a stream. The fluid should be centrifugated, spreads made from the sediment, stained and examined for the various bacteria with the oil immersion. The tubercle bacillus, *Diplococcus intracellularis meningitidis*, *Micrococcus lanceolatus*, staphylococcus, streptococcus, pneumococcus, bacillus of influenza, and typhoid bacillus are the chief causes of meningitis. The spread should be stained by appropriate methods."—(Arneill's *Clinical Diagnosis*.)

The meningococcus is a diplococcus, found both within and without the cells, and looks just like a gonococcus. It decolorizes by Gram's method. The presence of such a diplococcus here is sufficient for its identification. Cultures may be made on Loeffler's blood serum, at body temperature; colonies will develop in from 24 to 48 hours. The meningococcus is very hard to cultivate even on this medium, and it will not grow on the ordinary media.

DIAGNOSIS.

1. The jugular venous murmur is a murmur sometimes heard when auscultating the veins of the neck. It is a humming sound, and may be audible over the internal jugular vein just above the clavicle. It may be due to the change in calibre of the internal jugular vein as it passes through the cervical fascia; it may be due to pressure with the stethoscope; or it may be found in patients suffering from chlorosis or anemia, or tricuspid regurgitation; cardiac hypertrophy and dilatation with aneurysm have also been considered causes of this murmur. The flowing back of some of the blood from the right ventricle to the right auricle communicates an impulse to the venous blood entering the auricle from the superior vena cava.

2. The secondary skin symptoms of syphilis usually appear two to three months after infection. They are characterized: By not itching; by being of a copper or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical.

3. Eczema is an acute, subacute, or chronic, noncontagious inflammatory disease of the skin, characterized

primarily by erythema, vesicles, papules, or pustules, and, secondarily, by scales and crusts, and accompanied by itching and burning. The various forms of eczema constitute about 30 per cent. of all skin diseases. There are several varieties corresponding to the most predominant lesion. These may continue as such or terminate in eczema rubrum or eczema squamosum. The diagnosis of eczema is, as a rule, easy. The most distinctive features are: (1) Serous exudation; (2) the gradual merging of the patches into the surrounding healthy skin; (3) polymorphism of the lesions; (4) the symmetry of the eruption; (5) the marked itching and burning.

4. Girdle pain is a sensation as of a constricting band encircling the trunk. It is due to irritative processes in the region of the lower dorsal or upper lumbar nerves. It occurs in tabes dorsalis, chronic myelitis, injury or tumor of the spinal cord and inflammation or tumor of the meninges of the spinal cord.

5. Facial paralysis. "If the paralysis is of peripheral origin, involving the facial nerve only and not constituting a part of a hemiplegia, the eye cannot be completely closed, and the forehead cannot be wrinkled, owing to paralysis of the orbicularis palpebrarum and the occipito-frontalis. The tongue, if protruded, does not in reality deviate from the middle line, as may be determined by watching its relation to the central upper incisors, the genio-hyo-glossus not having been affected. The apparent deviation is due to the pulling of the mouth to the sound side. If the paralysis is of central origin, the upper branch of the facial is but slightly affected, the power of closing the eye and wrinkling the forehead is largely retained, and the tongue deviates toward the paralyzed side, as the genio-hyo-glossus usually loses its power and its healthy fellow is unopposed."—(Butler's *Diagnostics of Internal Medicine*.)

The reaction of degeneration appears in the peripheral form.

6. In suppurative phlegmon of the tonsil, "the onset is usually sudden, and the affection is ushered in by a rigor, high fever, and a feeling of malaise. There is persistent thirst and dryness of the throat, and the patient has the sensation of a foreign body being in the pharynx, with a constant desire to swallow. Swallowing is extremely painful, the pain shooting up to the ears, and the patient has difficulty in taking nourishment. The saliva accumulates in the mouth; the voice is thick and nasal; and the respiration impeded and noisy. If the patient can open the mouth sufficiently to afford a view of the back of the throat (which, however, is seldom the case), the inflamed parts are seen to be of a dull reddish-violet color. One tonsil is often more swollen than the other, and the corresponding anterior pillar of the fauces more prominent. The uvula is swollen and edematous, and is deviated towards the side on which there is least swelling. Suppuration occurs in from three to seven days; in adults it is usually in the peritonsillar tissue of the anterior pillar of the fauces, and extends into the soft palate. In children the pus sometimes forms in the substance of the tonsil. If left to burst, the abscess discharges itself into the mouth, and the patient experiences instant relief. The pus is always offensive, and if the abscess bursts during sleep, it may enter the air passages and cause septic pneumonia. The lymphatic glands in the neck are usually enlarged and tender, and sometimes they suppurate, giving rise to a diffuse septic cellulitis."—(Thomson and Miles' *Manual of Surgery*.)

7. Symptoms of inflammation of the frontal sinus: "Pain, unilateral or bilateral, over the frontal region, which is aggravated by assuming a stooping posture, coughing, blowing the nose, and nasal tones in speaking are characteristic symptoms. The disease may run its entire course without pain. More or less congestion of the nasal and conjunctival mucosa may be noted. The discharge from the cells is at first a thin, stringy mucus, later becoming mucopurulent. The discharge from the cells is sometimes very profuse and continues for a number of days. Upon inspection of the nasal cavity, the thick seromucus will be seen draining anteriorly and in the trough formed by the septum and bony structure dense mucus can be detected emptying into the middle meatus."—(J. J. Kyle's *Diseases of Nose, Ear and Throat*.)

8. "The symptoms of mediastinal tumor are: (1) Engorged veins on the anterior and lateral portions of the thorax, sometimes accompanied by cyanosis and edema of the skin. (2) A marked dyspnea, associated often with a harsh, brassy cough and pain. (3) Symptoms of pressure on the recurrent laryngeal nerves, causing abductor paralysis of one or both vocal cords, usually the left. (4) Dysphagia due to pressure on the esophagus. (5) Dulness over the upper portion of the sternum or adjacent portions of the thorax. (6) Rarely the x-ray shows a distinct shadow. (7) The heart and lungs may be displaced. (8) There may be a bulging of the sternum, which may or may not pulsate. If it does it has the forcible expansile pulsation of an aneurysm. (9) Palpitation of the suprasternal notch and of the deep cervical nodes may confirm the suspicion of a tumor."

"When an aneurysm has not eroded the chest wall it may be almost impossible to differentiate from a tumor. The cyanosis and venous enlargement are more marked in tumor and these symptoms are more progressive. The most valuable signs of aneurysm are the thrill to be felt and the bruit often heard over the sac, and the radiating pains to the arms and neck. The other signs of aneurysm are hoarseness from recurrent laryngeal pressure, dyspnea and dysphagia."—(Eisendrath's *Surgical Diagnosis*.)

In *pulmonary tuberculosis* there will be history of insidious onset, fever, emaciation, anemia, physical signs of consolidation; the lesion is most frequently at the apex, and sooner or later the sputum will contain tubercle bacilli. In *empyema* an exploring needle may find pus; there will be dullness over the effusion, while above the effusion the percussion note is generally higher than normal. Vocal fremitus and resonance are absent over the dull area, and the breath sounds are diminished or absent; there are high and irregular fever, leucocytosis, expectoration of offensive material, and redness in the intercostal spaces.

9. Five common conditions occurring between the pylorus and the ileocecal valve that are attended by hemorrhage into the lumen of the bowel: Duodenal ulcer, syphilitic ulcer of the intestine, tuberculous ulcer of the intestine, carcinoma of the intestine, typhoid ulceration of the intestine.

10.

HYDRONEPHROSIS.

1. A history of renal colic or of intense pain in the region of the kidney.

2. Commonest in hysterical women, after traumatism, and following repeated pregnancies.

3. Pain cramp-like, and may radiate to the pubic region. Dull, constant pain at times.

4. Abdominal tumor develops quite abruptly and disappears suddenly.

5. During the disappearance of the tumor the patient passes a large quantity of pale urine of low specific gravity.

6. The appearance of the tumor is decidedly intermittent.

7. There may or may not be disease of the prostate.

8. Jaundice rare.

DISTENDED GALL-BLADDER.

1. History of pain in the region of the liver. Pain radiates to right shoulder.

2. Occurs after middle life and after several attacks of gall-stone colic.

3. Pain may persist for several hours, and then disappear suddenly. Radiates to right shoulder.

4. Tumor may disappear suddenly, following which there is usually one or more copious bilious discharges from the bowel.

5. Urine bile-stained.

6. Tumor intermittent where it follows hepatic colic, always in right hypochondrium.

7. Prostate normal.

8. Jaundice persistent.

—(From Anders and Boston's *Medical Diagnosis*.)

11. In *chronic appendicitis* there is a history of one or more previous attacks in which no operation was performed, or perhaps the diagnosis was not made; attacks of pain occasionally occur in the right iliac

fossa; there are various digestive disturbances, such as constipation, diarrhea, flatulency; a tender mass may be detected on palpation over the painful area; the pain generally incapacitates the patient for a day or two.

Impacted stone in the right ureter causes colic, which comes on suddenly and occurs in spasms of excruciating pain, which is referred to the kidney and ureter and to the testis and penis. Collapse, cold sweats, nausea and vomiting, retraction of the testis, frequency of micturition and strangury are present. The x-ray may show the presence of the calculus.

12. *Edema due to renal disease* begins in the face and extends downwards, and is generally associated with pallor.

Edema due to cardiac disease begins in the feet and extends upwards, and is generally associated with cyanosis.

(To be concluded.)

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

COLLECTED REPRINTS FROM THE GEORGE WILLIAMS HOOPER FOUNDATION FOR MEDICAL RESEARCH. Volume 2, 1916-1917, 297 pages, illustrated. By The Department of Research Medicine of the University of California Medical School, San Francisco.

A MANUAL OF HISTOLOGY. By HENRY ERDMAN RADASCH, M.Sc., M.D. 580 pages, illustrated. Price, \$2.50. Published by P. Blakiston's Son & Co., Philadelphia.

SECOND ANNUAL REPORT OF THE STATE DEPARTMENT OF HEALTH OF MASSACHUSETTS. 576 pages. Published by Wright & Potter Printing Co., Boston.

A TEXT-BOOK OF OBSTETRICS. By BARTON COOK HIRST, A.B., M.D., LL.D., F.A.C.S. Eighth Edition, 863 pages, illustrated. Price, \$5.00. Published by W. B. Saunders Company, Philadelphia and London.

PRACTICE OF PEDIATRICS. Second Edition. By CHARLES GILMORE KERLEY. 913 pages, illustrated. Price, \$6.50. Published by W. B. Saunders Company, Philadelphia and London.

PRINCIPLES OF SURGICAL NURSING. By FREDERICK C. WARNSHUIS, M.D., F.A.C.S. 277 pages, illustrated. Price, \$2.50. Published by W. B. Saunders Company, Philadelphia and London.

THE PRINCIPLES OF HYGIENE. By D. H. BERGEY, A.M., M.D., Dr. P.H. Sixth Edition. 543 pages, illustrated. Price, \$3.50. Published by W. B. Saunders Company, Philadelphia and London.

A LABORATORY MANUAL AND TEXT-BOOK OF EMBRYOLOGY. Second Edition. By CHARLES WILLIAM PRENTISS, A.M., Ph.D. 411 pages, illustrated. Price, \$4.00. Published by W. B. Saunders Company, Philadelphia and London.

DIFFERENTIAL DIAGNOSIS. Volume 2. Second Edition. By RICHARD C. CABOT, M.D. 709 pages, illustrated. Price, \$6. Published by W. B. Saunders Company, Philadelphia and London.

THE ELEMENTS OF THE SCIENCE OF NUTRITION. Third Edition. By GRAHAM LUSK, Ph.D., Sc.D., F.R.S. 641 pages, illustrated. Price, \$4.50. Published by W. B. Saunders Company, Philadelphia and London.

A TREATISE ON CLINICAL MEDICINE. Second Edition. By WILLIAM HANNA THOMSON, M.D., LL.D. 678 pages. Price, \$5.50. Published by W. B. Saunders Company, Philadelphia and London.

CHEMICAL PATHOLOGY. By H. GIDEON WELLS, Ph.D., M.D. Third Edition. 707 pages. Price, \$4.25. Published by W. B. Saunders Company, Philadelphia and London.

DENTAL AND ORAL RADIOGRAPHY. By JAMES DAVID MCCOY, D.D.S. Second Edition. 179 pages. Illustrated. Published by C. V. Mosby Company, St. Louis, Mo.

PEPTIC ULCER.*

BY JOHN B. DEEVER, M.D.,
PHILADELPHIA, PA.

THE subject of peptic ulcer continues to hold its interest for the clinician, the surgeon, the bacteriologist, and the pathologist alike. By peptic ulcer we mean an ulcer of that portion of the gastrointestinal tract, the stomach, the duodenum, or the first portion of the jejunum, in which gastric juice is normally present. According to location, therefore, the ulcer is known as gastric, duodenal, jejunal, and marginal. Jejunal ulcer pure and simple is rare, yet it has been recorded and is therefore known as a distinct pathological entity. Personally I have never seen a simple jejunal ulcer. Marginal ulcer is a sequel of gastroenterostomy or a high enteroenterostomy and is by no means very uncommon. I have seen eight cases of marginal ulcer and operated six cases. Jejunal marginal ulcer is, I believe, almost unknown. I have operated one acute perforated jejunal marginal ulcer following a jejuno-jejunostomy; the patient recovered.

It has been estimated that from 3 to 7 per cent. of patients complaining of gastrointestinal disturbance are suffering from a gastric or duodenal lesion in the form of ulceration. From the material furnished by this relative frequency of the disorder, we have been enabled to draw a rather definite clinical picture of the typical case of peptic ulcer, the best description of which still remains that given by Moynihan in his monograph on duodenal ulcer. The etiological factors, however, that give rise to ulceration are not as yet so definitely known. As described by Bolton, based on careful histological studies, the initial lesions are localized necrosis of the gastric mucous membrane, localizing hemorrhage, and inflammation of the lymphatic follicles. The most common cause of necrosis is bacterial infection or its toxins circulating in the blood. Necrosis may arise in this way without a preceding hemorrhage or lymphatic inflammation, but hemorrhage is an actual and frequent cause of ulcer and is likewise due to bacterial toxins acting on the endothelial cells of the capillaries, thus paving the way for the local destructive action of the gastric juice. Finally, inflammation of the lymphatic follicles, particularly numerous along the lesser curvature of the stomach toward the pylorus, may give rise

to a submucous abscess which in turn, by rupture into the gastric cavity, allows the gastric juice to act on the base of the ulceration thus exposed.

Ulcers developing in one or the other of these ways would heal in a normal stomach, but when acted upon by the frequently hyperacid gastric juice they show a tendency to spread rather than to heal, and sudden perforation or hemorrhage is often the first indication of gastric ulcer. Or in the case of simple ulcer the tendency is to become callous with chronic peptic ulcer as the result. There is little doubt but that every chronic ulcer was at one time acute and began in one of the aforementioned processes, the chronicity resulting from failure of the healing process. Thus both the acute and the chronic ulcers, or, as I prefer to call them, the open, and the healing or healed ulcers, may be latent until bleeding in the former, and exacerbation of the latter gives evidence of their presence. Both types, therefore, are a menace unless they present early symptoms. While medical treatment may and in a number of instances apparently does lead to a healing process, especially of ulcer in the stomach, it is doubtful whether a true peptic ulcer, as distinguished from an erosion, ever actually heals under purely medical treatment. Although surgery cannot as yet lay claim to a hundred per cent. of cures, there is sufficient evidence on hand to show that from 75 to 90 per cent. of operated cases that have been so treated are either entirely relieved of symptoms, or so markedly benefited as to require no further medical treatment.

The fact that recurrence does take place in some instances after operation can hardly be considered as a valid argument against operation, especially in view of the fact that it is the exception rather than the rule, while the reverse is probably true with medical treatment. For is not every case that comes to operation an instance of a medical failure or failures?

From the cases with recurrence of symptoms after operation and from those developing marginal or jejunal ulcers, I have gained the impression that these undesirable sequels are more likely to follow in those cases which clinically presented very high free HCl and very high total acidity. An obvious deduction from this observation would seem to be the importance of counteracting the acidity of the gastric juice by diet and medication, in operated patients with unusually high acidity, for some time after operation. The recent work of Hamburger and Halpern (*Arch. Int. Med.*, 1916, xviii, 228) on the inactivating influence of pepsin, of phosphates, chlorides, and carbonates of sodium is suggestive.

*Read at a joint meeting of the Mount Sinai and the Jewish Hospital Clinical Societies, Philadelphia, March 26, 1918.

Excision of a chronic ulcer of the duodenum is, in my opinion, the best method of treatment. From the subjoined table it will be seen that in the 146 operated cases on which this paper is based 37 (30 duodenal, 7 gastric) were treated with excision and posterior gastroenterostomy. All recovered. But unfortunately excision is not always possible, especially when the ulcer is low down in the duodenum. In this location excision is not only difficult and sometimes impossible, but it may also be dangerous, so that oftentimes, especially for the occasional operator, a gastrojejunostomy must suffice. A great many surgeons, prominent among them Sir Berkeley Moynihan, consider the gastrointestinal anastomosis as of itself a sufficient cure for duodenal ulcer. While in full accord with this opinion, I nevertheless deem it the first duty of the surgeon to direct his efforts towards the removal of the diseased area, in other words, cut out the ulcer and follow with a gastrojejunostomy, and you will in all probability cut out the chance of recurrence. And while cutting, do not omit to do an appendectomy, if it has not already been done, and thus remove that obnoxious and most constant source of intraabdominal infection—the appendix. Inspection of the gall bladder and the pancreas is also obligatory and treatment should be directed according to existing conditions of the same. In duodenal ulcer located on the anterior and outer wall of the second portion of the gut, the pancreas is very often involved. It is a delicate organ and is easily affected by infection communicated not only by way of the blood stream, but also by way of the lymphatics from the gall bladder, the stomach, etc. Indeed, this of itself constitutes a valid argument for early operative treatment for duodenal ulcer.

Ulcer of the posterior wall of the duodenum can be satisfactorily exposed and dealt with only by approaching it through the interocolo-epiploic route, to which I shall later refer.

For gastric ulcer likewise, excision is the ideal operation. But here, too, conditions do not always admit its application. It is generally considered best suited for ulcers located at some distance from the pylorus, but it should indeed be the operation of first choice in indurated ulcers, irrespective of location, that is to say, pylorectomy or partial gastrectomy for pyloric ulcers on the lesser curvature where there is no extensive involvement of the stomach wall; circular resection where the latter is the case and excision through an anterior gastrotomy of an ulcer on the posterior wall or simple excision by way of the interocolo-epiploic approach. By this approach the posterior wall of the stomach, the posterior wall of the duodenum, and the pancreas are well exposed. A conservative selection of cases, however, is essential and excision should be attempted only in the absence of encumbering adhesions and where the patient seems able to withstand what often proves a rather tedious operation.

The series on which this paper is based include pylorectomy and posterior gastroenterostomy 27 for chronic duodenal ulcer, with one death and four for gastric ulcer, with no deaths. Subtotal gastrectomy was chosen in nine cases of gastric

ulcer and two of duodenal ulcer, all of the patients recovering.

Twenty-one chronic duodenal ulcers and a few chronic gastric ulcers were treated by posterior gastroenterostomy alone. There was one death in the duodenal cases.

The advantage of excision as against gastroenterostomy with or without plication of the ulcer is that the danger of hemorrhage from the ulcer is entirely removed. I have known hemorrhage from the ulcer after gastroenterostomy to occur and cause death.

While posterior gastroenterostomy alone for gastric ulcer accomplishes the most where the ulcer is located in the pylorus and causes obstruction; it is, even then, not so efficacious a procedure as pylorectomy.

In doing a pylorectomy the stomach and the transverse colon are delivered, the lesser peritoneal cavity opened, and the pyloric and coronary arteries ligated close to where the sections are to be made. With the index finger of the left hand in the lesser peritoneal cavity and carried to the posterior wall of the duodenum, the omental attachment to the inner wall is made prominent by the point of the finger. The latter is then forced through the omental attachment and the omentum grasped at the point of the finger with hemostatic forceps and cut away until enough of the duodenum is freed to permit the application of hemostatic clamps between which the bowel is amputated. The distal end is then closed, surrounded with a purse-string suture and invaginated. Next the omental attachment to the stomach, as far as the point where section is to be made, is grasped with hemostats and divided; two clamps are then applied and the pylorus cut away between the clamps. Both the stomach and the duodenum are cut through with a cautery knife. The opening in the stomach is then closed and the operation terminated with a posterior gastroenterostomy.

Pylorectomy is also indicated in ulcers on the anterior wall of the duodenum which are not amenable to excision. In these it is best to amputate the duodenum below the ulcer and follow with resection of the pylorus. Posterior gastroenterostomy with plication of the duodenum in this type of ulcer is apt to lead to restoration of the lumen of the bowel by absorption of the exudate, in which case the pylorus will again transmit much of the contents of the stomach, and the ulcer again be subjected to their irritation, with recurrence of symptoms as a possible result. This is another reason why excision of the simple ulcer is preferable to gastroenterostomy alone or gastroenterostomy with plication, as the plication is not usually permanent.

In the case of ulcers of the anterior and outer wall of the duodenum which are amenable neither to excision nor to pylorectomy, being too low for either, we must content ourselves with plication followed by gastroenterostomy, although it is not so reliable as excision. This was done in twelve of our chronic duodenal cases, three of which succumbed after the operation.

Careful selection of cases and judicious choice of operation for each case should insure good results. The lack of such can often be traced to

some fault in the operation chosen or in the technique, such as doing a gastroenterostomy alone when an excision is in order, or when a pylorotomy or subtotal gastrectomy should have been done. Or by not making the gastrojejunostomy in the proper axis of the stomach, or sufficiently close to the pylorus or to the end of the resected stomach; or making the proximal limb of the jejunum too taut; or lack of care in suturing the proximal limb of the jejunum so that its lumen will not be distorted; or carrying the first line of sutures too far from the line of the bowel directly opposite the mesenteric attachment and thus carrying the posterior wall of the bowel so high as to produce a spur which will interfere with the free circulation of the bowel contents directly onward and not through the gastrojejunostomy opening into the stomach, thus causing a vicious circle; or by making the opening too large or too small.

As already indicated, where the ulcer occupies the lesser curvature distal to the pylorus and infiltrates both walls of the stomach, circular resection is the proper procedure. In doing this it is not always necessary to add a gastroenterostomy to the operation. In our series of twelve circular resections we found it necessary to finish with a posterior gastroenterostomy in only one instance. The latter is indicated when induration is diffuse and the ulcer located at a distance from the pylorus. In such circumstances it is safer to terminate the operation by anastomosing the proximal jejunum to the antrum.

One of the most serious, if not the most serious, menace of chronic ulcer is, of course, perforation. This complication is said to occur in about 4 per cent. of all cases, but the proportion is probably greater if those cases only are considered that come to operation. In my experience in the Lankenau (formerly the German) Hospital it has been about 10 per cent. during the past two years. The patients all recovered, operation having been performed from two to eleven hours after the onset of the first symptoms; in one case, however, three days had elapsed between the first symptoms of perforation and operation. About 70 per cent. of perforations occur from ulcers on the anterior wall of the stomach, and about 18 per cent. on the posterior wall; the fundus and the cardia being only exceptionally the site of perforating ulcers. This is explained by the circumstance that the anterior wall of the stomach is exposed to the general peritoneal cavity, and is also subject to a greater degree of dilatation and contraction than the posterior wall, and is also more exposed to traumatic influences. The posterior wall, on the other hand, being more rigid and more protected, an ulcer developing at this site is more liable to develop perigastric adhesions from any peritoneal irritation that may occur, and, thus reinforced, it is neither so apt to perforate, nor, in the rare event of actual perforation, is it so likely to induce peritonitis.

Posterior gastroenterostomy, after the ulcerous opening has been closed, is the operation of choice in perforating peptic ulcer, but it should be done only by the experienced surgeon and not by the occasional operator. This was done in three of our perforated duodenal ulcers. In seven the ulcer

was plicated and a gastroenterostomy done, and in the eleventh case of perforated duodenal ulcer a sub-diaphragmatic abscess was incised and drained. In one case of gastric perforation the perforation was closed and drainage instituted, and in two others, after closing the perforation, the gastrointestinal anastomosis was made. There were no fatalities in any of the operated perforating ulcers. Excision of a perforated ulcer as a routine procedure I consider unnecessary. Seromuscular suture of the perforation with linen, without attempting to freshen the edge, is usually sufficient, and where the opening cannot thus be securely closed it may be done by suturing a tag of omentum over it, or the gastrohepatic omentum may be anchored down to the perforation, or the perforated area may be packed off with gauze, as is done in other parts of the abdomen. Drainage is, of course, essential.

In treating suspected marginal ulcers, a gastrostomy is advisable in order to clear up any doubt as to the presence or absence of the ulcer. Usually it is possible to excise the gastroenterostomy field and make a new end-to-end union of the proximal and distal jejunum, following it with a posterior gastroenterostomy at the site of the opening into the stomach made by cutting away the gastroenterostomy, or at another point. But it is better, I think, to close the opening in the stomach entirely, to make a new opening and to join the distal loop of the jejunum to it and the end of the proximal jejunum to the side of the distal limb. In certain cases, where the original operation was done for stomach ulcer, and the pylorus left open, and there is no longer any evidence of the disease, the opening in the stomach can be closed by cutting away the gastroenterostomy and then making an end-to-end union of the proximal and distal limbs of the bowel. I have done this with very satisfactory results.

During the two years, 1916 and 1917, and up to the present time—March 23, 1918—I have operated in the Lankenau Hospital on 145 peptic ulcers, with an immediate mortality of plus 4 per cent. (six deaths). Of these there were:

	Number	Deaths.	Mortality, per Cent.
Chronic duodenal ulcer ..	93	5	5.3
Chronic gastric ulcer	34	1	3
Marginal ulcer	4	0	
Perforated duodenal*	10	0	
Perforated gastric	2	0	
Perforated	2	0	
	145	6	4.1

*One case of perforated duodenal ulcer which arrived moribund and died without operation is not included in the above.

These ulcers were treated as in the table below.

In conclusion let me state that it must be borne in mind that from 3 to 7 per cent. of patients suffering from gastrointestinal disturbances have a gastric or a duodenal ulcer; that it is doubtful whether a true peptic ulcer, as distinguished from an erosion, ever heals under medical treatment; that surgery does not lay claim to 100 per cent. of cures, but there is sufficient evidence from followed-up cases to say that 75 to 90 per cent. of operated patients are either entirely relieved of symptoms, or so markedly benefited as to require no further medical treatment; that every one the subject of

gastric or duodenal ulcer runs one of four risks, chronic invalidism, with which neurasthenia is so frequently associated; sixty chances to one that carcinoma will develop on gastric ulcer, and that 10 to 15 per cent. of chronic ulcers of the duodenum and stomach will perforate, which, if not recognized immediately, means death, and that a small percentage will bleed to death. Let me beg of my hearers not to be afraid to "go over the top," not to be afraid to invade "no-man's land"; in other words, with courage, confidence, and faith, advise radical treatment as against temporary measures—dawdling. For the betterment of the afflicted, pacifists and slackers in medicine are as damnable, as useless, except in causing trouble, as they are in warfare.

	Number.	Died.	Mortality, per cent.
Excision, post. gastroenterostomy:			
Chronic duodenal	30		
Chronic gastric	7	37	0
Posterior gastroenterostomy alone:			
Chronic duodenal	21		1
Chronic gastric	2		
Perforated duodenal	3	26	4
Pylorotomy, posterior gastroenterostomy:			
Chronic duodenal	27		1
Chronic gastric	1	31	3 3
Plication, posterior gastroenterostomy:			
Chronic duodenal	12		3
Perforated duodenal	7	19	10 5
Gastrotomy, posterior gastroenterostomy:			
Perforated duodenal		1	0
Subtotal gastrectomy, posterior gastroenterostomy:			
Chronic duodenal	2		
Chronic gastric	9	11	0
Circular resection of stomach:			
Chronic gastric	11		9
Circular resection of stomach, posterior gastroenterostomy:			
Chronic gastric	1		0
Subtotal gastrectomy, entero-enterostomy			
Marginal	4		0
Closure perforation, drainage:			
Perforated marginal	1		0
Closure perforation, posterior gastroenterostomy:			
Perforated gastric	1		0
Closure perforation, gastroenterostomy:			
Perforated gastric	2		0
Incision and drainage subdiaphragmatic abscess:			
Perforated duodenal	1		0
	146	6	1 1

Included in the above there were: Cholecystectomy, 14.
Appendectomy, 93.

I ask you not to assume the position in ulcer that was assumed years ago in appendicitis at the cost of so many lives. Do not be satisfied to draw your conclusions from the outside, but come with the surgeon and look upon the inside, where the truth is revealed and the mystery is dispelled.

1634 WALNUT STREET.

SOME FUNCTIONS OF CONSCIOUSNESS.

BY GEORGE V. N. DEARBORN, M.D.,

CAMBRIDGE, MASSACHUSETTS.

PROFESSOR OF PSYCHOLOGY AND EDUCATION, SARGENT NORMAL SCHOOL, CAMBRIDGE; PSYCHOLOGIST TO THE FORSYTH DENTAL INFIRMARY FOR CHILDREN, BOSTON, ETC.

In these days when a few good psychologists and psychophysiologists are seriously proposing that science throw overboard even the term consciousness, it might prove worth while to consider briefly whether consciousness has not functions in this cosmos of ours that sanction its retention for the service it can perform in our psychological ship,—

which after all is no pirate craft, no submarine.

To my ideation, consciousness is that radiant which is left of a mind when its subconscious aspects have been subtracted. It is immediate awareness, sentient experience, direct and present. It is that wholly indescribable personal knowledge, direct acquaintance with something or other, which is known to all. It is the indefinable psychic aspect, so to say, of all living. It is the flowing actuality of that which in a previous essay I have denoted and in part connoted as cenesthesia. It is the surface of our stream of mind, in content forever changing, yet in its inherent nature as unchanging as the spiral nebulae to be seen and dreamed of in a winter's night. Forever one but forever multi-form; forever the most wholly intimate and imminent concept that the human mind ever can know. From such a standpoint as denotation of what I mean by "consciousness," it will be seen to have functions, purposes, usefulness, meaning-for-life wholly indispensable in our personal nature as we know it. Or, at any rate, such is my thesis now.

Four functions of consciousness (fusing, or fusible at least, into one, from a very broad standpoint) are readily distinguished, as my students already well realize: First, *dischronation* backwards, forwards, and to some extent within the "specious present." Second, *integration*. Third, *happiness* (or at least satisfaction) for its own sake. Fourth, *personal* (and therethrough perhaps cosmic?) *evolution*.

I. " . . . we learn
The while all change and many vanish quite,
In their recurrence with recurrent changes
A certain seeming order; where this ranges
We count things real; such is memory's might."

Thus does James Thomson crystalize for us the first of our four functions of human consciousness.

So far as is known to the present writer, the late C. S. Minot, histologist and embryologist at Harvard, was the first to employ the unusual word *dischronation* in the uses of psychology; but surely the term fills a want. Plainly, it is homologous to *dislocation*, the general function of the body as logically opposed to mind. In this case it is a displacement, in a figurative sense, in the time-series rather than in the spatial series. As such, as a *dischronator*, consciousness has use just as certainly as the material body has use among space-filling entities by its primal contractility and its resulting ability to move or *dislocate* material objects.

These terms are perfectly homologous and therefore of equal force.

In passing, it is noteworthy that in *dischronating* experiences, consciousness also *integrates* them into what practically, if not in theory, is a continuum. It thus gives us a temporal unification and consequent personal identity in a way homologous to that in which also it gives us (this is our second function) our spatial unification.

Dischronation as carried on by consciousness has as part of itself the convincing "associative memory" of the biologists, the lowest substratum of real value which the mechanist as such, already *rara avis*, allows to an epiphenomenal consciousness. They, if not we psychologists, ought to be thank-

ful for this much, for associative memory is of fundamental, indeed of wholly indispensable, importance for the right evaluation of pure mind. With only this much of use, and what it implicates, consciousness would be quite obviously knowledge that is of most worth, and its study a science by itself. Surely it is valuable for its own usefulness.

Dischrationation recalls, then, as well as memorizes, and affords the animal, whatever be his graded complexity, worm or man, a universal means by which it can vitally profit by its past experiences both pleasant and unpleasant, useful and harmful; and by its past dischrationations as much or perhaps even more than by the past immediate experiences. The common libeling of John Locke's philosophy involves usually the omission of this "profiteering" through the dischrationation of past memories and of past integrations. Without these mediate recalls, sensationism would have no persuasive facts on which to stand, much less to erect the firm structure of a philosophy on. With them, through an integrating power of dischrationation, sensationism proceeds on its career of persuasion and perhaps of universal psychologic conquest.

But even so, and with kinesthesia allowed all that belongs and is coming to it, it is impossible at present to accept Professor Warren's tang-estimation of the use of consciousness for intelligent living: "The value of consciousness thus appears to lie, not in any motor role, but in its furnishing the tang of life to each individual." Webster defines tang as "a strong or offensive taste; fig., a sharp specific flavor or tinge," etc. It may not be supposed that Professor Warren intended any such suggestion as this. But far more important in either event is the implication in other sentences of that article that consciousness must be outside of the determination of intelligent living, intrinsically as impotent as the odor, we may say, behind an automobile, because consciousness apart from neural activity can be no cause thought as a transformer of matter and of energy. But brave, yes, almost rashly bold, is the man who today would put his trust in any present definition or in any notion, even, of energy or of matter, and thus of causation!

But that, too, aside, why should it be taken for granted that consciousness is "apart" in any proper sense at all from "neural activity"? Leaving idealistic metaphysics out of it altogether for a moment with its hypophenomenalism, let us hear the very latest authoritative dictum of the physicists concerning the present status of matter and of energy:

"—the electron is made up of pure negative electricity and of nothing else, *i.e.* it contains no 'matter', as distinguished from electricity. Although it is difficult to give a direct justification of this assumption, it is nevertheless in harmony with all of the analogies of the situation, and is contradicted by none of the facts." Atoms made of electrons, electrons of electricity! The nervous eurrent, neurility, is generally judged by investigators to be some mode of chemi-electric progression on an ionic basis,—A. P. Mathews, for example, pioneer. The supposed break, then, in this our suggested consciousness-subconsciousness-neurility metabolism-protoplasm continuum must be just between consciousness and "cerebration" by way of

the subconscious aspects of mind. But fewer and fewer, seemingly, in practice notice this "break!"

But "epiphenomenon" or truer "hypophenomenon," it's all only one as soon as the thinker perceives that protoplasm alive and neurility and subconsciousness and consciousness are the phenomena of a quantum quid perhaps of which we know just one certain thing: That it is, in each individual, the 1. Some writers seem to forget that sometimes it is not a plain logical alternative, either this or that or nothing—that the "nothing" may prove to be just the saving grace that blots out all our psychologic sins. In this case, for example, it just may not be that consciousness either is causal in behavior or else a nauseating (or even lovely) epiphenomenon. For consciousness might be with the behavior-series in space and time and causality so intimately one and inseparable that to speak of it as causal were as superfluous and as misleading as to use the term living as an adjective qualifying protoplasm. Dead "protoplasm" is but the rotting, putrid sarcasm of living matter. In like sense and in like degree even, consciousness without causation in reality may be a paradox, a philosophic joke whereat our great-grandchildren will laugh in glee. "Those droll misgivings of a century ago!" they may say! Consciousness, in short, may prove to be the very *soul* of natural causality.

But the consciousness of man and of some of the knowingest brutes, at least, can look forwards as well as backwards, can anticipate no less than recall, and prophecy as well as remember. This marvel of epiphenomenalism has a cyclopean eye in its forehead as well as a wise occipital protuberance behind. Within the limits of its own personal amount of energy, initiative, and will, whether rational or "capricious" (that is, whether usual or unusual), each individual's consciousness more or less perfectly can determine what it will do; and can foresee that determination. This, quite as plainly as the other, is dischrationation, is dislocating in a figurative sense the consciousness of a later time into the present. On this process, in its phase of constructive imagination, nearly all progress, scientific, artistic, industrial, moral, depends. It plans our evolution.

In like manner, a certain amount of "selectivity" (James) is possible within the "present" experience, a selectivity in part temporal, a true dischrationation, though for the most part spatial (dislocation) or even causal.

As reaction in a possible reader's mind to the foregoing sketch of dischrationation, there is liable to be the objection that the writer is unwarranted in claiming that it is consciousness that dischrationates and thus has this process as a function. Herein, to refute such a complaint, is an opportunity, but I think not the need, for eloquent rhetoric and "heated" argument after the manner of those who debate the algebra of logic and similar antebellum wisdoms. I shall insist only, however, that it possibly may be a matter like pessimism and optimism, suffragism and its anti; a matter of personal *temperament*, that is, a way of coloring one's judgment. But I defy anyone to disprove my insistence that to one probably fairly sane mind at least this power of integrating a series in such a way as to be able to "look before and after" on the reality of events, is wholly *inconceivable* in a mechanism,

even of neurility, without that which we are terming consciousness. Mark that I do not say that it is inconceivable but only that I know that it is inconceivable by myself. Imagine if you please an elaborate electric floor-clock such as one sees in the living-rooms of wealthy clubs. Can my possible reader satisfactorily bring himself rationally to fancy such a mechanism of brass and steel having the power, to say nothing of the practice, of recalling a hesitation in one strike a week before (due to a bit of dust falling off an interior shelf); or of remembering the night when the two intoxicated men nearly knocked it over and cracked one of its delicate organ pipes?

I appeal that such processes of dischronation backwards are powers inseparable from that which we term consciousness; and to our rationality hard to be understood, properly speaking, as functions of mechanisms deprived of consciousness, that is, of in-organisms. And things that are hardly understandable or understood, pro tanto are for the seeker improbable, to him unlikely.

If dischronation backwards be so, then anticipation or prophecy is still more so, for it involves a "higher" sort of intelligence, one far beyond the mechanical performance of "material" neurones. If this be treason to the motivity of "mind"—make the most of it. But a dead neurone "performs" not at all; it merely decays.

II. Our second stated function of consciousness is *Integration*, and in the four "chief categories" of our experience: time, space, causality, and life.

Taking the empirical personality as a conscious going concern of mind and matter, unification certainly is not bestowed by any entity or being of us except consciousness. The nervous system, the hemolymph circulation, the hormones and koliones, and the musculature, to be sure satisfactorily integrate the body's parts into a working organism. But in the writer's humble judgment, the working unification of the phases of the mind into a "*working*" mind, and then of the mind with the body, is not explainable, so far as has been thought out by me, at least, without the agency of consciousness.

Professor Warren, does not hesitate to admit that it is his "*conscious experiences * * * that mean life*" to him. (I believe he would not object even to having this stated as the consciousness of his experiences instead of his conscious experience.) How "life" could have "meaning" apart from conscious experiences *integrated* into the evolutionary nexus, the social and personal "order," it is impossible for me at least to understand. Integration is the "highest," the most inclusive concept of which we know; realized, it is God himself. It underlies meaning, as consciousness underlies integration.

III. *Happiness* (or at least satisfaction) is our third function of consciousness in man and in brute. At its best, this tone is happiness, but as elsewhere I have insisted, always is it satisfaction so long as the individual remains a possible free agent toward his own life-destruction.

Here plainly enough lies the ultimate argument of philosophy for *the Necessity of Liberty*, and that the eternal quietus should be put once for all on autocracy, on militarism, on everything extant that

tends towards the dissatisfying unfreedom of personal mankind. "Give me liberty or give me death."

This function of consciousness needs even less argument than the two that precede it. It is on the same rational base as beauty, "its own excuse for being," for "beauty is truth, truth beauty; that is all we know on earth and all we need to know." Th. Harding Rand expresses it well in his sonnet "To a Deep-sea Shell":

"Fit for the palace of high Seneschal!
Inlaid with colors which the Tyrian King
Vain sought to rival on his royal scroll,
And echoing yet the ocean's trembling string:
Methinks the Master wrought this ivory hall
To please the love of beauty in His soul."

This is as good psychology and philosophy as it is poetry, and the writer has no notion of trying to improve on it in scientific prose. He insists, however, that beauty is a phase and a mode of happiness; and that precisely the same relationship holds here as there. Happiness is part of the "meaning" of life; to some hearts its chief meaning and even its only sanction.

Without consciousness, as even the most antique and mechanistic of my possible readers, it seems likely, would admit, happiness and satisfaction are nonsense-syllables and nothing more.

But after all, happiness does not depend on this argument just presented to force its claim that consciousness through it has one function at least—wholly indispensable in a motor personality in a material and *spatial* world. In the explicit statement of a point of view from the pen of Professor Warren already referred to we read as part of its summary: "The notion that consciousness, apart from neural activity, is an efficient cause of intelligent action is a survival of a prescientific conception of causation. To the modern scientist causation means transformation of matter and energy." Precisely. And every year as the relationship develops between pleasant emotion and efficiency and the larger expenditure of energy plainly motor, does it become more certain, more obvious, more commonplace that this tone of consciousness (namely, happiness, pleasantness, satisfaction) is knit inextricably and indissolubly with the highest motor success in living. The stheneuphoric index,⁶ in technical phrase in a *real* thing, not a fancy nor a bit of phantasy. It works either way. You can force the energy from the euphoric side just as surely as you can feel the euphoria follow from the sthenic side. It's a good rule, and it will work both ways. If Professor Warren prefers to leave such a relationship out of his own personal notion of causation, there are others aplenty, and more and more of them, think I, who will prefer to integrate a bit further—namely, a step at least into the newer conception of matter, of energy, and of mind. "Who then shall arbitrate," and set these three-fold bounds?

Personally, I see no way, in the light of recent conceptions, than to agree that if "it is these *conscious* experiences that mean life to me," these conscious experiences, so far as euphoric or dysphoric at least, are in that life, a part of the motor series which only provides the coarse adjustment, as it were, in our material world of space. But it is the fine-adjustment influence that gives reality, the two

moving ever in each other's work, part of the same enlightening empirical process. Arbitrary discrimination between consciousness and subconsciousness merging into neurility, in short is no longer right, but, a survival of the prescientific conception of conventional authority and habit of thought. Subconsciousness cometh into its own, and apace.

IV. Our last, fourth, function of consciousness, as noted above, is *personal evolution*, through namely, evil, and pain and unpleasantness in particular: Job's great enigma.

The ancient religious argument for struggle and victory thereafter (as opposed to denial and asceticism especially) in my opinion is perfectly sound and probable; we win our real personality only through personal effort in overcoming every besetting influence. Our thesis might do not a little with this in the way of defining a true function of consciousness, for effort, personal, direct, immediate, inhibitory effort in a contest with new conditions, is conscious, and related to evolution if anything whatever be. It is a "meaning of life," part of the essential "intelligence" of living, which Professor Warren in his recent article,^{*} ascribes to mechanism as such. But thus he deems it "incomplete" (p. 620).

Here in our fourth function certainly is one of its incompletenesses! Just as happiness (or at least satisfaction) is an incompleteness, so is pain and so are the reactions in our consciousness, whether painful or only unpleasant, of many of the manifolds of evil that beset our little day.

The argument here is much like that, *mutatis mutandis*, of the preceding function of consciousness. Unpleasantness and pain can no more be crowded out of the psychomotor nexus which is in each case ourselves, than it can be avoided or ignored in the daily routine. The words which would make it seem "apart" do not convince, for they ignore a point of view (already set forth elsewhere and outlined above) which gets to the heart of the matter. This maze is too intricate to be solved by any old-time rule of thumb, presuming as it does to dictate what energy and consciousness are and just where the supposed demarcation between them. "The epiphenomenon is no less a datum of existence than the hypophenomenon," says our defender of this "damarcation"—terms whose very use in such a relation implies that they are but aspects of a noumenon that is an integration, an empirical continuum.

In such a continuum "causation" oftentimes loses none of its efficient working-value for life; but it does lose whatever of meaning it has for logically contrasting epiphenomenon and hypophenomenon in one totality of immediate experience, for example, which both modern theory and universal practice (assumption) suggest as anxiety. In worry and fear, mind and body come together, each "causal" towards the other.

Here we once more see the estimable conservatism and regard for antique authority which objected to "the psychology without a soul"; to the James-Lange theory; to "the new psychology"; to the subconscious phase of mind; to "mind-stuff"; to the application of psychology to pedagogy, etc., etc., etc., which with our own eyes we have seen opposed seriatim and—welcomed, as gradually their friendship to reason in each case became plain.

Now we are objecting to an outworn notion of energy and to its border-lines,—not much unlike the objection which biology has so successfully made to physicist's idea that work must have always a spatial element.

The sciences need to compare notes oftener, and to help each other with their new points of view. For universal integration is the spirit of science, and for psychology in an especially large degree continuity means progress; and progress Life.

A ROUTINE METHOD OF EXAMINATION AND STUDY OF THE GASTROINTESTINAL TRACT BY THE ROENTGEN RAY.*

By I. SETH HIRSCH, M.D.,

AND

I. J. LANDSMAN, M.D.,

NEW YORK.

FIRMLY rooted in the domain of diagnostic medicine, the roentgen examination is to-day esteemed indispensable in the study of disease of the gastrointestinal tract. There is, however, an increasing confusion regarding the methods and routine of the examination, which makes it imperative that an effort be made toward the adoption of a definite, systemic routine, based on similar fundamentals, made with similar means, recorded in similar terms.

In the adoption of a particular routine there are many factors to be considered. The size, variety, and class of hospital service or private practice, equipment of the laboratory, the convenience and comfort, the technical and economic status of the patient; all these factors have a bearing on the question. Thus a routine suited to a special sanatorium devoted to gastrointestinal diseases, however effective it may be, cannot be applied to an active, mixed medical and surgical service in a general hospital, where the cases are numerically great and distracting in their variety.

Economic necessity demands that the examination be simplified, in order that it may be within the reach of all who require it, rich and poor alike, and that it may become a routine in clinical examinations and not a special procedure, to be utilized only where examinations are inconclusive.

It is essential, therefore, that the method capable of general application shall have the virtues of expediency, efficiency, and economy (of time and material), and that it shall meet the demands made upon it in both hospital and private practice.

Basis for the Examination.—The consideration of the functional capacity of an organ must concern itself with the study of its anatomy and its physiology. That part of the physiological func-

*From X-Ray Department of Bellevue Hospital.

tion of the stomach with which we are concerned is, in a general way, its motility and secretion, and just as there are physiological disturbances without anatomical deviations, so there are anatomic deviations without apparent physiological changes.

In a general way, therefore, it may be stated that organic pathological conditions manifest themselves by: (1) Deviations in the morphology; (2) disturbances in motility.

Method of Examination.—The methods of examination utilized are as follows:

1. Transillumination of fluoroscopy (roentgenoscopy): (a) General; (b) special—orthodiagraphy.

2. Photographic method—roentgenography: (a) General examination: Single plate—target plate, distance 24-30 inches; direction: dorsoventral, ventrodorsal, oblique, vertical, horizontal, right lateral; (b) Special examinations: Stereoroentgenography—two plates with deviation of tube two and one-half inches, the relation of plate to part remaining unchanged; teleroentgenography—tube plate distance 80 inches; serial exposures; polygram—two to four exposures on the same plate.

The general examinations 1 and 2 are followed in every instance, and the special examinations only where the condition demands it.

Routine.—Preparation for the examination: The patient refrains from the evening meal, taking a soapsud enema before retiring. All medication is to cease before preparation is instituted.

The examination is now made for the determination of the following points: A. What is the gastric motility? B. Is there hypersecretion? C. What is the intestinal motility? D. Has the proper meal been properly taken?

A. Motility Examination.—For convenience, the examination is begun with the motility test. A carbohydrate meal with 20 per cent. contrast salt, bismuth, or barium, is taken for breakfast, and the examination is begun six hours later. No food is taken in the interval.

In stout subjects, the contrast salt may be increased to 30 per cent. Bismuth subcarbonate and barium sulphate are most commonly used. The objection to the subnitrate is the occasional presence of nitrites with its danger of poisoning. The objection to subcarbonate is that it neutralizes the free acid in the stomach, diminishes motor activity and interferes with normal action of the pylorus. The importance of these disadvantages has undoubtedly been exaggerated. According to some observers, particularly Hertz, the most preferable salt is oxichloride, since it does not diminish the acidity of the gastric juice, is not toxic, is palatable, easily suspended and is one and one-half times as opaque as barium sulphate, and slightly more so than the subcarbonate. At this day, however, barium sulphate is the salt most commonly employed. The advantages are its low cost and the absence of disturbances of the physiological condition. It does not in any way affect the acidity of the gastric juice. It also has the additional advantage of being more rapidly expelled from the stomach than the bismuth preparations, its evacuation beginning almost immediately after administration. It is important to bear in mind that the *barium sulphite* is a dangerous poison and should not be mistaken for barium sulphate. The disadvantages of barium sulphate are that it is less opaque than bismuth and much larger quantities are necessary and that it suspends with difficulty. The dose of the barium is necessarily much larger than the bismuth, as much as eighty to one hundred and twenty grams being occasionally necessary. The movement of a barium meal through the gastrointestinal tract differs somewhat from the bismuth meal, not only in its more rapid expulsion from

the stomach but its more rapid movement through intestine.

It has been stated that bismuth exerts a special activity in the small intestine, which delays the progress of both solids and fluids and also induces reflex disturbances, which prolong the emptying time of food stuffs, therefore, for the purposes of studying the digestion and expulsion time of foods, barium is the preferable salt. Among substances which have been used is zircon oxyde, known as contrastin. This is much lighter in weight than the other substances used, interferes less with the normal taste of the meal, and is inexpensive. Cerium and thorium dioxide have also been utilized.

Gastric motility is the result of the reaction between (1) content, (2) tone, (3) peristalsis, and (4) pyloric patency.

1. The content is the two-hundred gram carbohydrate meal, a foodstuff normally more rapidly expelled from the stomach than any other (generally completely in six hours), calling forth no excessive secretion and tolerated even in the presence of the most extensive disease.

If the contrast mixture is to be used for the purpose of studying merely morphology, the medium is unimportant, provided the suspension is sufficient to clearly outline all parts of the stomach. However, in motility study, the nature of the suspension media is very important. For the various foodstuffs vary in their expulsion time, the carbohydrate being most rapidly expelled, the proteids next, and the fats remaining in the stomach for the greatest length of time. Carbohydrates and fat both begin leaving the stomach soon after they are ingested, but the carbohydrates leave rapidly, while the fat leaves slowly, so that the maximum expulsion is attained at the end of two hours, when it slowly drops.

It is because of its rapid expulsion that the carbohydrate is particularly valuable for the purpose of studying gastric and intestinal motility, since the studies may be begun almost immediately after the ingestion of the meal and surely within the first hour. Fats, however, are expelled with more regularity and in a generally slower way, so that where prolonged study of gastric morphology is desired the bismuth fat meal may be utilized. Proteids, however, pass out of the stomach very slowly, the process frequently beginning only at the end of an hour. It is important, too, to note that the amount of secretion present in the stomach after the ingestion of a proteid bismuth meal is much greater than with a fat or carbohydrate meal. Therefore, as a test for hypersecretion the proteid meal has its disadvantages. It may also be of value as a method for stimulating spastic contraction. As a motility test the carbohydrate meal has many advantages: It is palatable, easily prepared, its expulsion time is short, beginning soon after ingestion; it is the least burdensome and least irritant to a diseased mucous membrane; it does not cause too extensive flow of secretions, it does not have too great viscosity, and does not diminish gastric peristalsis.

The carbohydrate meal may consist of farina, oatmeal, cream of wheat, etc., cooked in milk or water, and with enough sugar and salt added to make it palatable. The meal should be semifluid and total about 200 gram. The meal originally described by Rieder is prepared as follows: 40 grams of bismuth subcarbonate or 80 grams of barium sulphate are thoroughly mixed with enough water to make a thick emulsion and to this a tablespoonful of milk sugar is added. The milk sugar serves a double purpose. It improves the taste and also overcomes the constipation effects of the bismuth. The emulsion is added to the cooked meal and thoroughly mixed in order to obtain an even distribution.

The oatmeal meal must have a certain density and size and is prepared as follows: Take one teacup of water with a pinch of salt and bring it to a boil and add one teacup of Quaker oats. Boil twenty-five minutes in double boiler. To this milk and sugar are added.

Motility test should not be made with bismuth suspended in buttermilk or fermented milk.

It is important to note that inference regarding motility of one meal cannot be transferred to another meal

of a different foodstuff, and that it is better to establish a certain standard with one particular meal and to judge any deviation from this particular standard.

Hertz has suggested a normal standard meal as follows: Porridge, 7 ounces; milk, 1 ounce; bismuth or barium sulphate, 2 ounces.

The bread and milk meal is as follows: White bread (cut in cubes), 2 ounces; milk, plain or malted, 8 ounces; barium sulphate or bismuth acacia, 2 ounces. Boil, stir, and pour over bread. Add sugar ad lib.

Held has suggested a meal of eggs, toast, cereal, and milk, thus containing the various foodstuffs. He believes that such a test has more delicacy than the simpler meal.

Carman uses 4 ounces of well-cooked wheat breakfast food, with milk and sugar.

For intestinal tract (motor function) known quantities of mixed diet to which is added a definite amount of bismuth with each meal is given during the first day. During the second day (when examination begins) same diet is maintained without bismuth, and the study is then continued until bismuth is evacuated.

2 and 3. The part which tone and peristalsis play in the evacuation of the stomach will be discussed later.

4. The pyloric patency in an organically normal pylorus is governed by gastric secretion through nervous influences. Among the most important of the reflexes controlling pyloric patency is Mehring's reflex, the inhibition to the closure reflex by the presence of acid in the duodenum. The secretion of the normal amount of acid fluid, also, in a measure acts through the nerve influences to regulate the motor activities.

It may, therefore, be stated dogmatically that, with normal acidity, in an organically normal stomach six hours after a carbohydrate contrast meal, as above described, the stomach contains no bismuth—the content has been expelled.

There is no denying that a normal stomach may empty itself of the above meal in some cases in three hours, but an allowance must be made for physiological variations, for various psychic and physical influences, and these are fully met by a six-hour test.

A very rapid evacuation may indicate a pathological condition. There may be an insufficiency of the pylorus, due to a primary achalia, to a diffuse scirrhus or syphilitic infiltration of gastric wall (the pyloric opening being held gaping) to duodenal ulcer or to a gastro-enterostomy opening.

There are cases in which at the end of six hours the stomach is empty, but the bismuth mass has not progressed very far; in other words, it is still distributed in the duodenum, jejunum, and the head of the ileum. If in such a case peristalsis is active, the motility test should be made at the end of three and four hours and careful search made for early lesions.

B. Secretion.—Further study will show that the air bubble or "Magenblase" is oval, long, and narrow, for there is but little secretion in the normal stomach, containing no food.

To study the secretion more accurately, two capsules, one containing bismuth and air and one only bismuth, are administered. The former floats on the surface of the fluid and the latter sinks to the greater curvature. The position of the two capsules is noted. The estimation of the vertical distance between them gives the amount of fluid present. The form of the stomach and the width of the fundus and corpus must be taken into consideration. When considerable secretion is found, the inference that free HCl is present is justifiable. A bismuth residue without the hypersecretion suggests carcinoma, because it indicates that no free HCl is present.

The capsule test has been used for many purposes. The psychic effect of the appetite may be studied by

swallowing two capsules on a fasting stomach and stimulating the appetite, and noting the separation of the two capsules by the inflow of gastric juice. The expulsion time of the liquid foods or medicines may be studied in this way.

The bismuth may also be used for the determination of the amount of free hydrochloric acid in the stomach. The capsules of Schwarz, made of goldbeaters' skin, containing 4 grams of bismuth and 25 grams of neutral pepsin, are used for this purpose. The patient is given a test meal in the morning, containing 200 grams of tea and a known amount of bread. The capsule is swallowed and the patient reclines on the left side. A fluoroscopic examination is made at the end of one and one-half hours. If the capsule has been digested the bismuth will be seen as a small patch, coating the inside of the stomach, and the inference of a hyperacidity is justifiable. If the capsule is digested in two hours a mild degree of hyperacidity is present; if in two and one-half hours, a normal acidity; in three and one-half hours, a mild subacidity. In an acidity, it is not digested in five hours.

C. Intestinal Motility.—The head of the bismuth column is at or near or slightly beyond the hepatic flexure, the tail is in the terminal coils of the ileum.

D. The entire bismuth shadow sums up what experience has shown is that of a meal of two hundred grams. Thus the four questions asked above are answered.

Disturbed motility may manifest itself either as hypo- or hypermotility.

Hypomotility.—The stomach contains a residue. This is now studied as to its (a) size, (b) location, and (c) shape.

(a) *Size.*—1. Minimal residue, which does not exceed a shadow of 1 inch by 1 inch. This is not important as a sign of pathology, because such a small amount of bismuth may remain in the stomach till the ninth hour and may be explained on the basis of a muscular insufficiency or ptosis with atony. The distribution of the bismuth in the intestine and the consideration of the other factors mentioned as concerned in motility will indicate its true significance.

2. Small residue, which may vary from two inches square to about one-quarter of the content of the stomach. Such a residue is not usually expelled until the twelfth hour and is rarely found without pathological changes in the gastric mucosa.

3. The medium residue may be as large as one-half of the content and its final expulsion time may be more than eighteen hours. It is usually due to pyloric or lesser curvature ulcer or to new growth.

4. A large residue, which may consist of the entire meal, the final expulsion time being more than twenty-four hours, sometimes several days.

If hypersecretion be present, there will be noted above the shadow of the bismuth residue the lighter shadow of the gastric secretion and the air bubble or "Magenblase" may now be a hemisphere with a considerable diameter, in which fluid waves may be demonstrated.

(b) *Location.*—It may be located either to the right or the left or on both sides of the median line, above or below the umbilicus. The nearer normal the gastric tone the better the residue is embraced by the gastric walls and the more likely it is to lie near the pyloric end and to the left. Conversely the more to the right the residue lies, the more atonic and dilated the stomach. The greater the hypertony the further above the umbilicus it lies; the more the atony the further below.

A residue lying on both sides of the median line, with the bulbus to the right of the median line, indicates uncompensated pyloric stenosis, usually due to long-standing pyloric obstruction. And the more chronic the ulcer, the further the residue extends beyond the median line.

An isolated fragment of bismuth in the area which should be occupied by the stomach (usually to the left of the median line) demands careful analysis, since it may be retained in the crevice of an ulcer. If to the right, it may indicate duodenal ulceration.

The residue associated with a lesser curvature ulcer lies to the left of the median line; the pylorus vertically placed and more or less parallel to the spine, and the shadow of the bulbus duodeni, also to the left. This is due to the retraction of the lesser curvature resulting from the ulceration.

A residue with smooth outline, lying with its vertical axis to the left of the median line suggests careful scrutiny of the lesser curvature for ulcer.

A residue in the duodenum or jejunum should be looked for. This is most common in the bulbus, which it may fill wholly or partially, or as an isolated fragment may be located in a niche, spring from the bulbus.

(c) *Shape*.—The shape of the residue varies. It may be (1) an irregular fragment, such as may be located in a niche; (2) an oval shadow, partaking the shape of the portion of the stomach contour, which embraces it, and either pyloric or fundal; (3) a crescentic mass sagging in the very lowest portion of an atonic stomach (old pyloric ulcer); or (4) a rounded mass having a ragged contour toward the pylorus and smooth toward the corpus (carcinoma of the pylorus).

Though a large residue has considerable significance without the consideration of any other factor, still it is important to think of it not by itself, but in relation to tone and peristalsis, pyloric morphology, etc. An increased vis a tergo applied to the passenger (meal) may push it through a narrowed passage (pylorus).

The small residue is found in compensated pyloric stenosis and duodenal disease. Adhesions do not produce a residue unless the adhesions be due to an ulceration.

Such a residue as is given in either of the last two groups is absolutely pathological of pyloric obstruction, due either to organic stenosis or spasm.

Atony and ptosis rarely produce a residue. If present, it is usually minimal and is with ease differentiated from a residue due to organic changes by the consideration of the other factors concerned in the motor functions of the stomach, the tone and peristalsis, both of which are diminished in atony and increased in early stages of ulcers. In the later stages of ulcer, however, the atony and dilatation of uncompensated pyloric stenosis is to be differentiated from the partly functional atony by noting that in the organic atony the residue lies in the median line and the pylorus is usually displaced considerably to the right, while in the latter the residue, if present, is smaller, lies to the left of the median line and the pylorus is usually in the median line below the level of the umbilicus. Then, too, the examination in the left lateral position or with the pelvis raised will cause expulsion of the residue through the pylorus. It cannot be denied, however, that with more attention to the proper preparation of the meal and the various details attending its administration the residue in pure atony will not often be found.

Even a minimal residue in a stomach exhibiting excessive tone and excessive peristalsis has a characteristic significance—an organic lesion—while the same residue in a subtonic or ptosed stomach, with feeble peristalsis and high acidity, may be explainable on the

basis of functional causes or muscular insufficiency. Again, a scirrhus infiltration of the pylorus may exist and yet, because of pyloric incompetency, the stomach may be empty in three hours. To find a residue of one-eighth of the gastric content, with normal peristalsis, tone, a morphologically normal stomach need not indicate an ulceration or obstructive lesion; but such a residue with evidence of hypertony and excessive peristalsis, though in a morphologically normal stomach, means a pyloric spasm or obstruction. Thus hyperistalsis and hypertony with high acidity and suggestive clinical evidence would, even if the emptying time is normal, demand a reexamination before the lapse of six hours. By itself, therefore, though giving the key to the examination, the residue, except as indicating gross pyloric stenosis, has no pathognomonic significance.

On the other hand, the stomach may be empty, but the position of the bismuth mass in the intestine, duodenum, jejunum, or ileum may indicate a hypomotility and lead to the inference that there is a gastric hypomotility. The actual emptying time must then be determined by repeated tests.

Hypermotility.—The cause of this must be studied in relation to tone, peristalsis and pyloric patency.

The rapid evacuation may be due to excessive tone and peristalsis in a stomach with a normal pylorus—on the other hand, with an incompetent pylorus—the rapid evacuation may take place in a stomach whose tone and peristalsis are normal. The causes of the excessive tone may lie in the intrinsic form and structure of the stomach, or, as is most commonly the case, it is due to reflex causes, arising from the ileo-caecal, duodenal, gall bladder, hepato-pancreatic region. The excessive peristalsis is most commonly reflexly induced when the pylorus is not stenosed. The pyloric incompetency is either due to intrinsic infiltration—scirrhus-syphilis or is reflex from the duodenum, liver or pancreas.

B. *Sedimentation Test*.—It becomes necessary for us to proceed with the examination and to study tone and peristalsis and then the morphology of the tract. This necessitates the administration of a contrast mixture. It is best, however, for thoroughness and accuracy to begin the examination with a non-suspended mixture of contrast salt in water. This is commonly called the "Sedimentation test." The mixture consists of one ounce of barium or bismuth, stirred with four ounces of water. The salt sediments rapidly through the water to the greater curvature and pylorus, from which point, by fluoroscopic palpation, it may be spread over every part of the stomach wall. Thus, lesions on the anterior or posterior walls are made out, which, with the stomach completely filled, would escape detection. By this procedure we study:

1. The method of filling the stomach. This should be studied by individual swallows of contrast mixture. The bolus drops from the oesophagus, flows along the lesser curvature, halting in the pars media. When the tone is increased the bolus may halt for a longer time. Only after palpation or deep breathing does it glide along the lesser curvature to the pylorus and then the greater curvature. On the other hand, if atony exists, it may drop from the oesophagus to the surface of the retained fluid in the stomach and then rapidly sediment directly to the large residue below. Thus the deviation in the course of the stream or in the method of filling gives many important clues.

2. Mucous membrane irregularities. The irregularities in the lumen produced by the ulcer-bearing

area, the niche, the diverticulum or tumor formation may be outlined by the mixture—the granules of bismuth being deposited within these crevices. The above morphological data may also be determined by the usual suspended contrast mixture, but because the stomach is thus completely filled with contrast mixtures, small penetrating or perforating ulcers on the posterior wall may be overlooked.

The search for the ulcer-bearing area must be made in every case in the vertical posture in every oblique position and then in the horizontal posture. When this is done linear projections which have been erroneously dubbed slit ulcers will not appear as slits but as typical niches with air bubbles. The ulcer-bearing area does not always show as a rounded bud; it may be flat, irregular or pouched; but the end result is something added to the bismuth shadow of the stomach in contrast to a tumor formation which subtracts something. This niche most commonly springs from the lesser curvature, less commonly from the posterior wall, least commonly from the greater curvature. Its size and shape varies with the shape and size of the ulcer and the direction of its protusion. Considering its roentgen appearance as a bud, it may be spoken of as being sessile or pedunculated, and the isthmus connecting it to the stomach may be long and narrow. The summit of the bud may contain an air bubble. It may be visible before the administration of the sediment mixture, by virtue of a retained fragment of bismuth from the motility test or because of its air content.

3. Stomach Tone. The tone being that property of the gastric muscle by which it maintains the contents in tubular form, a normally tonic stomach will almost be as full (fluid level) with five ounces as with fifteen.

The position of the upper level of the gastric content in its relation to the position of the lowest point of the greater curvature may be used as an index to tone after a meal of definite quantity. Extreme gastropsis may be present with normal tone and extreme atony with little ptosis.

Hypertony exists in the early history of most cases of gastric ulcer and persists late in duodenal ulcer.

Tonus is the basis on which peristalsis manifests itself. Before peristalsis appears, tonus exists. As regards time, they bear an almost simultaneous relationship to each other. This is what some observers are groping at when they talk of systole and diastole, besides the peristalsis.

Peristalsis is considerably dependent on the presence of tone. The atonic stomach shows a much impaired, diminished and disordered peristalsis. Through the agency of nerve impulses, general asthenia and the emotional state produce their effects on the alimentary tract by impairing movement, through abolishing tonic contraction, and therefore rhythmic peristalsis. The tone of the stomach is increased in hunger and it is claimed that the sensation of hunger results from the tonic contractions in an empty stomach.

Hypertony may show itself also as a type of spasm. The spasm may be of the entire stomach (total gastropasm), or local segments of the gastric wall may be tetanically contracted. When total gastropasm takes place, the capacity is naturally diminished, the resistance to the distention of the

lumen is increased. An air bubble may no longer be visible in the vertical posture.

The local spasm may exist in one examination or several and be absent in others. The result of this spasm or spastic indrawing is to divide the stomach into two sacs, giving the so-called hour-glass stomach.

The spastic incisura may be visible in the oblique examination and not in the sagittal and because of the falling of the shadow of the upper sac over the lower it may not be apparent in the horizontal position, when it can be seen in the vertical. When located opposite the niche of an ulcer the contraction gives the stomach a characteristic ulcer-hour glass appearance. Because of fibrous-tissue production, perigastritis and scarring, the spasmodic hour-glass type may be transformed into a true organic hour-glass stomach, in which the spasm, though it still exists, plays but a small part.

4. Antral Activity. The action of the antrum may be observed because the water is not retained in the stomach and the peristaltic activity begins almost immediately; thus the hyperactivity of the early ulceration or the lessened waves of the atonic antrum, resulting from old ulcerations, may be noted. As the contrast salt sediments to the pylorus, however, only the peristalsis of this part is visible. The details regarding peristalsis are, therefore, more carefully studied when the stomach has been completely filled with a suspension mixture.

5. Pyloric and duodenal patency. As a rule, even the spastic pylorus is patent to water and whether the delay at the pylorus is due to spasm or obstruction may be determined by the use of antispasmodics. One-half to $\frac{3}{4}$ of a grain of papaverine is administered one hour before the meal. If pure spasm be the cause, the residue will be much diminished or absent. If obstruction is present the retention will be greater. The abnormal evacuation of achalia gastrica or when the pylorus is gaping from infiltration of scirrhus carcinoma, is in marked contrast to the slow evacuation where spasm or obstruction exists.

In order, therefore, to test the pyloric patency, it is necessary to cut out the closure reflex resulting from the acidity. This may be done in the following way: The patient receives the ordinary bismuth meal, and after this has been evacuated 220 grams of water are administered, with two bismuth capsules, one containing air, which floats on the surface of the liquid, and one which sinks to the greater curvature. The space between the two capsules, which corresponds to the depth of the liquid, is noted. This distance may be studied on the screen every twenty minutes, until the capsules are on the same level, when the inference may be drawn that the stomach has become empty. The average time consumed is about sixty to seventy minutes in normal cases. If both carbohydrate and water detention are present an organic stenosis exists.

6. Pyloric morphology. Either by pressure on the pylorus or blocking at the pars horizontalis and pars superior, the pylorus may be studied or the bulb of the duodenum may be filled and overfilled for the study of form, peristalsis, antiperistalsis and mobility. The morphological deviation of the pylorus, resulting from pyloric ulcer, may be various. As a rule, it becomes pointed but occasionally exhibits no defect, only a lessened density of shadow over the very pyloric end. A ring-like defect, at the expense of the pylorus and antrum, must be differentiated from a defect due to a new growth. The

old deep ulcers of the pylorus usually have many adhesions and considerable fibrous tissue, which may be responsible for this appearance. The morphology of the duodenum will be studied later.

In many cases a diagnosis is possible at this stage of the examination. The existence of many of the lesions of the stomach and duodenum in the pylorobulbar region and lesser curvature makes this examination with the sedimentation test an important and sometimes the only one necessary. It is, however, insisted upon that the examination in all cases be completed.

C. General Morphology Examination.—Though we are now in a better position to appreciate the significance of the motility test, it is, however, only when the examination is finally completed and the morphology thoroughly studied that all the various findings in the examination attain their full significance. Therefore, in all cases, except where a contraindication exists, we proceed to complete the gastric examination by administering a large quantity, twelve to sixteen ounces of a thoroughly suspended contrast mixture, barium sulphate in buttermilk, and to the main morphological study of the stomach, duodenum, and small intestine.

More or less permanent suspension may be made with the aid of substances, as acacia, terra alba (Fuller's earth), or by means of such complex mixtures as that of Gouravisch: Potato flour, 75; milk, 1,000; almond syrup, 250; barium sulphate, 400. This is treated with 2 liters of boiling water and, while being stirred, brought to a boiling point. The liquid is boiled one-half an hour until 400 c.c. are evaporated, and then cooled and a teaspoon of a solution of formalin 1-1000 added. This has the consistency of cream and keeps well.

The morphological studies may be made according to the following scheme:

STOMACH.—Type: (1) Hypersthenic, (2) Sthenic, (3) Hyposthenic, (4) Asthenic. The nomenclature of the four main types of status (Mills) is applied to the stomachs, which these individuals should normally possess.

Each of the type, when it conforms to the habitus of the individual is orthotonic, when it does not, it may show (a) Excessive tone—hypertonicity. (b) Diminished tone—hypotonicity. (c) Absent tone—atonicity. Thus, the orthotonicity of the sthenic stomach may, as a result of long-standing pyloric stenosis, be changed to atonicity. The suffix tonic-ity in this scheme now has a clear meaning.

The Schlesinger nomenclature has caused much confusion.

Axis: Vertical, oblique, horizontal.

Size: Normal, small, large.

Position: Fornix—relation to diaphragm; greater curvature. Lesser curvature—Relation to interspinous line and median line. Pars pylorica—Axis, length, position, antrum.

The position of the stomach depends on the status of the individual; tonicity of the stomach and abdominal wall musculature, position of adjoining organs and state of filling of intestines. The division of the stomach into fornix, corpus, pylorica (the antrum being considered the most distal part of the pylorus, is the simplest, clearest and sanest division. These data should be given in every report to the clinician, since they permit him to plot the position of the stomach on the abdominal wall.

The measurements are made in the vertical posture, the hepatic flexure. From the further study of the

Tone: Normal—orthotonic. Variations—hypertonic, hypotonic, atonic.

Outline: Incisura, niche, defect: Location. Number (single, multiple); size: (Narrow, wide); form: (Deep, shallow, irregular); permanence.

These deviations must be differentiated from the normal variations in outline: (1) Splenic or costal depression, (2) incisura angularis, (3) sphincteric hiatus, which should be studied as to its size, position and form; (4) rugae folds, usually brought out by pressure; (5) depressions due to colon.

The contractures with or without the niche formation give the bi- or tri-ocular stomachs (hour-glass deformities). The resulting isthmus may be long or short, wide or narrow, centrally or laterally placed. All these data should be noted and recorded.

Peristalsis: The waves are studied under six headings: (1) Origin, (2) Altitude, (3) Length, (4) Frequency, (5) Direction, (6) Symmetry.

Hyperperistalsis means not only that the frequency of the waves per minute is increased, but that the wave has its origin nearer the cardia and that its altitude exceeds its length; in other words, its depth is increased. When the altitude exceeds the length the wave is deep and small. The shallow wave has a great length but small altitude. The wave may be of a different type on the curvatures. The study of the direction of the wave may disclose antiperistalsis—a phenomenon of great significance in the stomach.

SMALL INTESTINE.—*Duodenum* (bulbus).

Type: Triangular, Spherical, Irregular.

Position: Relation to pylorus.

Size: Normal, Small, Large, Indeterminate.

Outline: Incisura, Defect, Niche. Location, Number (Single or multiple); Size (Narrow or wide); Form (Deep, shallow, smooth, irregular).

Evacuation: Complete, incomplete, rapid, slow.

The niche of the ulcer and the spastic contracture are responsible for the majority of the deformities in outline of the duodenum. The bud of the ulcer may, of course, be located on any wall, but it most commonly is situated on the inner border. The spastic contracture may be on the same or on the opposite side to the ulcer or be present on both sides. The deformity is most common on the internal border of the triangle.

Duodenum (villous).

Type: V-shaped, U-shaped.

Position: Descendens, Horizontalis, Ascendens, Duodenojejunal angle. It may be displaced right, left, up or down, depending on disease of adjacent organs.

Size: Small, medium, large.

Outline: Defect, niche, diverticula.

Peristalsis: Segmental, mass movement, pendulum.

Jejunum.

Size.

Patency.

Peristalsis.

ILEOCECAL REGION.

Cecum.

Type.

Position—relative to interspinous line.

Size.

Outline.

Peristalsis.

Mobility.—The bismuth mass begins to appear at the cecum in three and one-half to four hours after a carbohydrate meal. At the end of six hours the cecum is filled, the tail of the mass lying in the terminal ileum, the head of the column being near the hepatic flexure. From the further study of the

colon a re-examination at ten or twelve, twenty-four, thirty-six, forty-eight, sixty, seventy-two hours may be necessary, depending on circumstances.

Ileum.

Position—relation to cecum.

Size: The size of the individual coils cannot be measured, excepting the terminal part, which is about a finger's breadth.

Patency: Six hours after bismuth carbohydrate meal several coils are visible in the right pelvis, the terminal portion rising perpendicularly to the cecum. At the end of ten hours the ileum should be empty, the head of the column is near the splenic flexure, the tail at the cecum.

Mobility.—It is at this time that the appendix is most frequently visualized. Its size, shape, position, state of filling, and mobility may be studied and sensitiveness to pressure determined. At the end of twenty-four hours the study of the colon may be undertaken.

ABDOMINAL COLON: *Ascending, Transverse, Descending.*—Form (transverse): No loop; loop to right; loop to left; bilateral loop; abnormal looping.

Position: Distal, proximal.

Size.

Outline—Defects: Permanent, temporary.

Tone: The haustra are due to the tonicity of the longitudinal muscular bands. When the tonicity is lost the colon shows as a smooth, cylindrical shadow. The haustra disappears when the are passively stretched from distention of contrast enema.

Haustra: Origin, extent—Large, small, regular, irregular.

Peristalsis.

(a) Segmental—These movements are due to contractions of the circular muscular fibers. They have no directive power.

(b) Haustral—This is a true peristaltic movement consisting of a wave of contraction preceded by a dilatation. The movement is slow and the progression limited.

(c) Mass—These occur but two or three times daily and result in massive displacements of the contents for a considerable distance. Over a portion of the colon the haustra disappear. Then a sharp constriction appears and the mass moves forward with lightning-like rapidity, leaving a thin trail of bismuth behind in the contracted gut. As the movement ceases the haustra reappear.

(d) Pendulum—This is due to varying degree of contraction of the unstriped muscle of the mesocolon, whereby the colon varies its position in the abdominal cavity. There are many other factors concerned in this inconstant position of the colon.

(e) Antiperistalsis—This is most common in the ascending and in the right half of the transverse.

PELVIC COLON.

Sigmoid.—Type: Dextropelvic loop, median loop, levopelvic loop, no loop.

Size. Mobility.

Rectum.—The rectopelvic portion of the colon is best studied in the dorsal position.

D. *Mobility* is studied by (1) Variation due to posture. (2) Variation due to position. (3) Variation due to retraction of the abdominal muscles. (4) Variation due to palpation.

The entire examination should be made fluoroscopically, the morphological studies should be made radiographically, in order to provide a permanent record, and to minimize the possibility of error.

The fluoroscopic examination in the morphology study should be carried out both in the horizontal and vertical postures, the patient also being examined in the lateral and oblique positions. In this way morphological deviations will not be overlooked, and the mobility of the stomach may be estimated.

The data having been noted should be reported to the clinician either in the negative or positive phase. After the data have been stated, the pathological findings should be isolated and the inference from these findings drawn.

So reported, the examination becomes valuable in that it permits the forming of a concept as to actual conditions and the correlation to them of the clinical findings.

Thus a report in a certain case may be given as follows:

The stomach is of the sthenic type, and normal in size.

Its axis is oblique.

The lowest point of the greater curvature is at the interspinous line, two inches to the right of the median line.

The lowest point of the lesser curvature is four inches above the interspinous line, and two inches to the right of the median line.

The pars pylorica is to the right of the median line, long, its axis to the corpus being oblique.

There is no defect in the gastric outline.

There is hypertonicity.

The peristaltic wave is increased, the waves being of small amplitude, numerous and symmetrically disposed, and have their origin at the cardia.

The antrum shows deep contraction.

There is rapid evacuation of the pyloric contents.

The bulbus duodeni is generally triangular in shape, lies to the inner side of the antrum, and shows a marked deformity in the outline, the defect being due to a smooth incisure on the right lateral wall of the bulbus and a niche formation on the left lateral wall. The bulbus does not change its position, either by posture or by retraction of the abdominal wall. There is sensitiveness to pressure over it.

Examination six hours after a carbohydrate meal shows a medium-sized residue in the pyloric end of the stomach, and a small residue in the bulbus.

The head of the bismuth column is in the lower part of the descending colon, the tail is in the last six inches of the ileum.

The colon is morphologically normal.

The pathological findings in this case are: (1) Hyperperistalsis. (2) Hypertony. (3) Pyloric incompetency. (4) Duodenal deformity. (5) Pyloric and duodenal residue. (6) Immobility of the bulbus. (7) Displacement of the pylorus to the right. (8) Hypermotility (intestinal).

These findings indicate the presence of a penetrating ulcer of the duodenum.

A further report is then given after the 24-hour examination.

In the foregoing exposition all the available knowledge of the gastrointestinal tract as furnished

by the x-ray examination has been utilized. From time to time, as the investigations have disclosed new data and observations, the scheme and the significance of the data have been amplified, verified, or corrected, but as a whole it has remained practically unchanged since 1912.

Synopsis.—1. In the examination of the gastrointestinal tract, the morphology and motility must both be studied.

2. The motility is to be studied by a carbohydrate meal in definite proportions.

3. The examination is to be begun with the motility test.

4. The location of the bismuth meal after six hours gives important indirect and direct information.

5. The morphological examination should be begun with a sedimenting mixture.

6. The mixture for the final morphological test should be a contrast mixture in suspension.

7. The morphological examination must be complete, thorough, covering the entire tract, made with a fluoroscope as well as with a plate, and based on a definite scheme of analysis.

8. The report of the examination must state: (a) The data obtained; (b) the pathological findings isolated; (c) the diagnosis based on these pathological findings.

11 EAST SIXTY-EIGHTH STREET.

SOME EDUCATIONAL PROBLEMS OF RACE HYGIENE.

BY EMANUEL S. BRODSKY, M.D.

WESTPORT, CONN.

NEUROLOGIST AND PSYCHIATRIST OF THE ST. VINCENT'S HOSPITAL, BRIDGEPORT, CONN.; ASSISTANT MEDICAL SUPERINTENDENT OF THE WESTPORT SANITARIUM; FORMERLY PHYSICIAN OF THE STATE PSYCHIATRIC INSTITUTION IN THE CANTON OF LUZERNE, SWITZERLAND.

BY race hygiene we understand consideration of those conditions which favor the normal breeding and the physical and mental development of the race. The question of race hygiene involves the most important and serious problems of social hygiene, comprising practically all problems associated with the question of education, heredity, marriage, and progeny, both existing and prospective.

From the medical standpoint our society falls into three different groups. The first group is composed of normal individuals, able to resist the evils of the world, well equipped mentally and physically to adapt themselves to, and struggle with, existing conditions. The second group consists of neurotics and other peculiar characters, with weakened mental and physical resistance. Some of these may break down occasionally, or become insane when their environment is not good, and when their constitutional ability—mental and physical—becomes inadequate to the burdens of life. The third and, to the physician, the most important group is made up of the large number of feeble-minded, including also imbeciles and criminals.

Those familiar with the question of insanity and feeble-mindedness in this and other civilized countries, are well aware of the fact that the number of mentally unfit in asylums, hospitals, and at large

has been increasing during the past several decades at a more rapid rate than the growth of the general population. The number of insane in asylums in 1880 was 86.6 inmates per 100,000 of the general population, while in 1910 the number had risen to 232 per the same number of the general population.

The census shows that there were 234,055 insane patients under treatment in institutions in the United States on Jan. 1, 1917, and it is generally estimated that the total number of feeble-minded in this country exceeds that of the insane. According to estimates of the Federal Census Bureau, the population of the United States increased from 91,972,266 on April 15, 1910, to 102,826,309 on Jan. 1, 1917, an increase of 11.8 per cent. The insane in institutions, according to the Federal Census of Jan. 1, 1910, and the census of the National Committee for Mental Hygiene of Jan. 1, 1917, increased from 187,791 to 234,055, an increase of 24.64 per cent.

In the asylums of New York state there are 35,000 insane. In Chicago alone in the year 1915 were arraigned before the criminal courts 125,000 delinquents, all mentally abnormal. The number of insane and criminal defectives outside institutions is several times larger, because, as a rule, only those insane or feeble-minded who represent an obvious mechanical menace to society, or who become a considerable burden to their families are placed in institutions. Therefore, taking into consideration the above figures, and assuming only an equal number outside institutions, we find that one person out of every 170 is insane in New York State, and one out of every 14 is defective in Chicago.

Assuming that New York has as many feeble-minded in proportion as Chicago, and that Chicago has proportionally as many insane as New York, we conclude that the average percentage of insanity and feeble-mindedness is over one per cent (one out of every 92 is insane or feeble-minded). The question of insanity and feeble-mindedness is thus a very serious one, and preventive measures along these lines are one of the most important problems of the present generation. Although we do not know all the factors producing such a rapid deterioration of the race, we do know a few which justify the discussion. With these it is imperative that the public be made familiar.

An individual is the result both of the tendencies which he acquired through the germ plasm (sex cells of his ancestors) and the effects produced upon him by his environment. For instance, alcoholism, as such, cannot be directly inherited, but the mental or the weakened moral stamina is transmitted to the child, and should he remain in his father's environment, or in an alcoholic environment, he also will become alcoholic.

Intense struggles for existence, resulting from the present forms of industrialism and competition, play a very important part in weakening the race, and the result of this weakening shows itself in prostitution and criminality. It is well known that prostitutes and criminals are recruited from an element whose moral resistance is considerably reduced. Nevertheless to remain unaffected in the present speed of life, sometimes requires a com-

plete human being with perfect intellectual features. Our age of growing industrialism and competition is thus revealing itself in immigration, war and destitution.

That the economic factor plays a serious part in promoting degeneration of the race, is evident from the report recently published by the Children's Bureau of the U. S. Department of Labor, a report based on the study of mental defectives in New-castle County, Delaware.

This report reveals a close connection between poverty and mental defects. Of 212 cases of mental defects studied, only four or five were in well-to-do families, and the majority were found in an environment making normal standards of living impossible. It would be wrong, however, to assume that poverty is, in all these cases, the cause of feeble-mindedness. A great many individuals are poor because they are defective, because they have never learned a trade, or because they never developed the ability for adaptation and self-support.

The sort of immigration existing at present is not a desirable one for the simple reason that it occurs under abnormal conditions. An individual who is compelled to find a new fatherland for his free development, and to seek a basis for existence in a new country, goes through a real "brain fever." He is torn away from his own soil and traditions, and finds himself helpless as a child, without a language, without a trade, under conditions to which he cannot adapt himself. The strain is so intense that a large number of men and women go through serious physical and mental changes; the women (for example) cease to menstruate, become depressed, and suffer a weakening of constitutional resistance. In time immigrants may recover from the shock and adapt themselves, but the children of such individuals are likely to inherit the broken resistance of their parents' constitutions, and to fill up the ranks of the second group of our society: the class of neurotics and the insane.

Another factor promoting deterioration is syphilis, which is disseminated chiefly by prostitution and inheritance. Syphilis has become a universal menace, and undoubtedly weakens the race. According to the reports of the Surgeon General of the U. S. A., twenty per cent of the white recruits are affected with syphilis; yet the percentage of syphilitics among army men is much lower than among men of a similar class in civil life.

Alcoholism also plays an important part in promoting crime, destitution, and moral and physical deterioration. While alcoholism in many cases is the result merely of environment or of bad habits, in a greater number of cases it is a manifestation of mental and physical sickness. Both syphilis and alcoholism are factors in promoting deterioration of the progeny, thus creating defective types.

Heredity, in certain conditions, becomes an important factor in promoting degeneration of the race. It is not sufficient to say that a certain condition can be inherited; it is important to study the conditions under which the disease can be transmitted to the progeny.

The elements of heredity are carried in the chromosomes of the sex cells, both male and female, but only those features can be transmitted to the germ-plasm (sex cells) which have what are called

determiners. These determiners are hypothetical material transmitters of each separate characteristic of the individual, or the so-called unit-character. In order to be passed on to the progeny, features or characteristics must therefore have a determiner. If a disease has no determiner it is not transmitted. Determiners may themselves be of two sorts, either recessive or dominant. For example, parents themselves free from the disease but having the neuropathic taint of their ancestors will produce several healthy descendants, and may or may not give rise to one who is diseased. But the several apparently healthy descendants are apt to carry the disease in a determiner of a recessive character.

In considering advisable mating, this fact becomes very important. In establishing laws similar to those existing in certain States—the laws of negative eugenics (laws preventing progeny)—it is necessary to draw conclusions not only from the qualities of the individual alone, but also from his determiners. Thus an individual may be diseased, but as long as he does not carry any objectionable determiners in his germ plasm, he will be capable of procreating healthy children. On the other hand, the person under consideration may appear to be normal, and yet, because he carries the disease in recessive form, may procreate diseased children.

What science has accomplished up to the present time regarding the laws of heredity, has proven to be correct in cases of certain neuropathic conditions, idiocy, and feeble-mindedness. These laws, according to the Mendelian theory and the latest observations of Rosanoff, Orr, and others, are as follows:

1. Both parents affected, all children will be affected.
2. One normal parent with neuropathic taint from one grandparent, the other parent neuropathic; half of the children are normal, but capable of transmitting the neuropathic make-up to their progeny (*i. e.*, they are carrying the determiner in recessive form).
3. One parent normal from pure ancestry, the other parent neuropathic; all children normal but capable of transmitting the neuropathic make-up.
4. Both parents normal but with neuropathic taint from one grandparent; one-fourth of the children will be normal, and not capable of transmitting the neuropathic make-up to their progeny. Half of the children will be normal, but capable of transmitting the neuropathic make-up, and the remaining fourth will be neuropathic.

It is estimated that about 30 per cent of the general population, without being actually neuropathic, carry the neuropathic taint from their ancestors, and are capable, under certain conditions, of transmitting the neuropathic make-up to their progeny. In connection with the foregoing, there exists the so-called sex-limited inheritance, which means that the determiner is dominant in males, and recessive in females. In hemophilia (bleeder disease) for instance, males are affected, but the disease is transmitted exclusively through the females, who themselves do not suffer from it. Progressive muscular atrophy, likewise, has a recessive character, affecting males only, although females are capable of transmitting the disease.

The strength of heredity was illustrated unusually clearly by cases reported in the October, 1916, issue of the *American Journal of Insanity*. Half a dozen individuals immigrated to this country in the seventeenth century bringing with them Huntington's chorea. The result of the propagation of these individuals is 900 choreics of the same type, all absolutely unfit for society. It ought to be made clear that, chiefly because of the confusion regarding the limitation of each, great disagreement exists regarding the relative effects of heredity and environment. Many influences commonly considered heredity, are in reality purely environmental. For instance, a toxic state in one or both parents affects the ovum, the spermatozoon, or both, giving rise to a defective impregnated ovum. For instance, if the conception took place during a state of intoxication, the development of the ovum is affected, and a defective child is the result. This is the case of an environmental influence of pre-natal character. Similar examples of post-natal factors are those which interfere with the growth of the normal child, such as poor nutrition, or nutritional disorders during the first year, and other similar conditions.

However, while the factors (undesirable immigration, syphilis, alcoholism, and heredity) mentioned above, are the most important in producing deterioration of the race, faulty education and environment also play a large part. To better the race, we shall have to go through a process of re-education and rebirth through social and individual reforms. This will require all the intelligence of the race, and all its capacity for conscious sacrifice. Social reforms are imperative, but unfortunately they are very remote. Such conditions will have to be established that war is impossible, and that immigration will not be the result of competition, poverty, or religious persecution. The struggle of life will then be less intense. The problem of to-day is the effort to produce strong, resistive and uncompromising individuals. While it is impossible to revolutionize the individual at once, the work for an ideal race could be begun immediately. Education, having in view the principles here advocated, should begin from childhood. Parents and the school should co-operate in producing these conditions, and promoting these principles in the community.

Let us attempt now to make a direct application of what has been said to the schoolroom itself. Entering any typical class, we can easily find representatives of the three groups spoken of before. We see expressionless, thick-lipped children with large heads, who manifest indifference, lack of appreciation and silliness. They are the defective group.

The children of another (the second or nervous group) are very different. They are delicate, well made in body, with finely shaped heads, delicately cut features, and fine skin. They are apt to complain of headaches, broken sleep, and malaise. Not that they have any definite disease; on the contrary they are rarely confined to bed. But they are not strong, and any exertion, walking, for instance, can make them very tired. Their body weight is subnormal, but their minds are above normal, and they are very clever. These are the

children who are given to mannerisms; they contract the eyebrows and protrude the tongue when engaged in writing or performing a difficult task.

They show their mental activity in their movements, and in the play of their facial muscles combined with their vivid expression.

These children are overemotional from their very earliest years, and are very susceptible to neuro-pathic disturbances. Advantage is very frequently taken of this overemotionalism in bringing them up, and sentimental mothers overdevelop their children's sentimentality. The nervous children are usually timid, overscrupulous and restless. Their capacity for affection is developed to such an extent, that in later life they fear reproach, and stand criticism badly. Yet if the sentimental side of their lives is upset in any fashion, they immediately sink into a state of depression. If their education had been directed towards teaching them to feel less, and to use a more discriminating judgment, such unfortunate consequences could have been avoided.

Such children should be taught that every feeling or emotion is dangerous when carried to excess, and that absolute reciprocity in affairs of sentiment cannot always be expected. When children are quite young, they should become accustomed to making prompt decisions, and to systematizing their work. If they are directed along certain lines suitable to them, with wise understanding, the almost fatal catastrophe of their lives can be easily avoided.

Also to be found in the schoolroom are children representing our third group—the normal children. They stand with heads erect and arms at their sides, with a direct gaze, calm expression, and fixed attention. We observe no mannerisms among them.

Proper education of the child will play a serious part in preventing deterioration of the race. This education should be based upon preserving the child's energy, recognizing his character, and developing the *psychical* mechanism necessary for creating an uncompromising individual, who will possess high moral and resistive powers. The old saying: *Mens sana in corpore sano* (a sound mind in a sound body) should be applied inversely also. Where there is a sound mind there is a sound body, because physical equilibrium depends a great deal on the strength of the mental faculties.

The child's character and inclinations are shown at the age of four or five. At this period of life he is liable to set free his personality in a surprising and marvelous way. The school will have to promote the development of the child's intellectual features, hampering him as little in his personal inclinations, if they are not defective. The study of the nature of the child should be the basis for teaching. The child should have freedom of action in order to fully express his inner life in outer activity, and an opportunity to act as much as possible in the realm of his personal experiences; *i. e.*, he should be given an opportunity of educating himself. His brains should not be overloaded with things which he cannot understand, or which cannot be conveyed to him by his sense organs. At the age of seven or eight the character of the child should be established in such a way

that its further development would bring him into the period of puberty as a normal individual. Faulty education does not promote the development of character. Infantile intellectual features of it are transmitted into the period of physical maturity. Considering all this we see the need for establishing a mechanism of "suppression."

Up to the age of four or five a child does not distinguish good from evil—any more than he realizes the existence of the sexes. At that age, also, or even when a little older, he is usually able to compromise by using his imagination, when he cannot obtain what he wishes.

A child, for example, desires to have what he sees, and when this is impossible or difficult, he begins to imagine that some object which he does have is what he has been striving for. If he wants a horse, he takes a broom, starts to ride upon it, and imagines that it is his horse. This compromising tendency occurs without any pain or serious mental processes—the imagination playing the part of an adjustor.

From the time that a child begins to distinguish good from evil, he demands likewise more reality, and does not satisfy himself with his imagination as much as he did before. Consequently it becomes necessary to establish another *psychical mechanism*, which must help him to obey the principles of normality. Modesty, which is the guardian of innocence, has to be built up at this time, and established in full force.

All this is especially important with regard to sexual tendencies, which are likely to assume a wrong tendency in early childhood. The establishment of a mechanism whereby *modesty* in its ethical and esthetical aspects, will be the *regulator of the suppression of bad tendencies*, is what we should aim for from the age of five or six, for, at the age of ten or twelve, we need its full force. This mechanism, when established, is utilized until the age of puberty and later, and is necessary for every normal individual. *And normal is that individual who can suppress everything that is wrong, i. e. against social and individual ethics. Those individuals who cannot suppress or control their sexual or antisocial impulses at all fill up the ranks of the criminals. The neurasthenic compromises himself all the time by an unsuccessful or partial suppression.* The normal individual must be successful. We need a race without compromises, able to control their instincts, when these are anti-racial.

While the child, up to ten or twelve years, suppresses his evil impulses unconsciously through modesty, the youth and the adult suppresses them more consciously. The established mechanism becomes in the end a reflex process, and aids the individual throughout the rest of his life in controlling undesirable tendencies.

Everyone is familiar with the fear of punishment in a child. It is frequently cultivated in raising children. In fact it is, in certain cases, a very important adjuvant in child training, and, in many cases, is not as wrong as some good-hearted mothers are likely to think.

This fear is also a reflex process, and is acquired through training; it stimulates an inhibition of things which are wrong. Modesty is a broad psy-

chological basis for establishing this fear reflex, and should be the only basis for every ethical and moral suggestion. Some authors call this reflex "acquired fear" and point out that it is rapidly cultivated in highly sensitive children; it is cultivated in the normal child with greater difficulty, and it is still more difficult, if at all possible, to cultivate in a feeble-minded or defective child. The educator must remember, however, that undesirable inhibitions are also likely to be established, and that this necessitates the utmost care in the training of the nervous and sensitive child, because the sensitive child loses an established habit with more difficulty than it forms it.

The training of the child unquestionably involves its education in sex hygiene, which deals with problems that normal human life cannot possibly avoid, and which each individual must be prepared to solve for himself. Even at the age of five or six, the child asks questions pertaining to sex. The principle which educators have to bear in mind in answering these queries, is to avoid a silly reply.

Children are very observant and an unsatisfactory answer will only cause them to be more inquisitive. Undoubtedly it is a difficult thing to advise any parent just what to say and how to say it. It is easier to suggest how to conduct sex education at the age of twelve or thirteen. At this age it is best to give the biological aspects of propagation, and at the age of sixteen the boy or girl can be made familiar with the hygiene of sexual life.

The four books written by Dr. Winfield Scott Hall of Chicago, and issued by the Board of Health and Public Instruction of the American Medical Association, are adapted for sex education for intelligent children between the ages of twelve and seventeen. The child will also need supplementary explanations from intelligent parents.

Sex education in schools is a new thing, and little experimented with, either in America or in Europe. Adequately informed parents are the best persons to teach the elements of parenthood and sex relations to their children.

This work must be carried on without injuring modesty, and should, on the other hand, promote genuine innocence, purity, and the sanctity of family life, as well as lead to health and physical morality.

The idea of a clean mind in a sound body may be inculcated by teaching that the productive functions are present for a higher purpose than mere sexual gratification, and that they should be restrained by reason and self-control, and exercised only in the legitimate way prescribed by marriage. "It is a cardinal sin against youth to deny it the knowledge which would safeguard it against ignorant exposure to dangerous infections." But it is important to conduct the education without arousing the mind to dwell upon the subject unduly, which causes needless alarm, depression, or overstimulation. The risk in some cases is worth taking. "Better a year earlier than an hour later."

Such knowledge will function completely in many lives, and will work appreciably in many others.

What are the practical measures which would lead to the purification of the human race? It is clear that the question of feeble-mindedness involves the most serious problem. Society suffers

most from this class. It is enough to remember that the unrestrained productivity of the defective and delinquent classes is appalling—abnormally large families among them are the rule. The economic burden from these dependent classes may become unbearable, and the social contamination from this source is a very real menace. Our knowledge is not yet sufficiently full and definite to warrant considerable procreative restraint of certain physical and moral types, which are inherently inferior. Nevertheless, it may be assumed that, if individuals of criminal and feeble-minded types could be made to remain childless, nothing would be irretrievably lost to the race. Ultimately the feeble-minded will have to be segregated or sterilized, and the criminal class segregated. It is interesting to note, in this connection, that the offender who is normal in mind and body reacts to punishment in such a way that the theory of the "deferent effect" seems to be valid. Not so the defective, the victim of imperfect mental equipment, the slave of addiction, etc., do not react normally to punishment. Those of the last category are therefore more in need of a psychopathic ward than of a criminal institution. The prophylactic measures against feeble-mindedness should begin in the school, where the character of the child ought to be studied with an eye to criminal and defective conduct. Defective judgment, abnormal temper, bad habits, and the character of the environment should also be watched.

Placing in a proper environment will correct a great many habits, and arrest the development of criminal tendencies. The underlying physical condition should, of course, not be disregarded. The utilization of this defective element for society is not an impossible problem. Measures against alcoholism, prostitution, and venereal diseases will also constitute part of the preventive measures against feeble-mindedness.

To cope with this problem will require not only individual co-operation, but also great radical changes in our form of life and government. Prostitution at present is the concomitant of capitalism and militarism, and "is stimulated by the starvation wages of the working girl."

Prostitution is the manifestation of weakened moral stamina, forced by two factors: economic pressure and sexual instincts. As marriage is prohibitive for the poor girl, she is forced by her weakened moral stamina into prostitution. On the other hand, "the young man of the middle and higher classes, who has a future before him, usually does not approach a girl of his own class until he has reached the required position, and is looking for a constant regulator of social relations—prostitution—a regulator which breaks and destroys the bloom of the young girls of the poorer classes." He promotes prostitution more than the male representative of the poorer classes, who cannot afford this luxury, and who usually marries early.

In order to assist the propaganda and to promote the measures of race hygiene principles, we shall have to establish mental clinics for diagnosis and medical treatment of these defectives, and mental hygiene classes for those who need and desire training and instruction. The propaganda will attempt to spread knowledge that will appeal to the

altruistic instinct, and thus move those seriously genetically deficient to voluntary celibacy. It ought to seek to cultivate the productive instinct. The old saying: *Fortes fortibus generantur* (strong are borne by strong) should be the logical conclusion drawn from the application of biological knowledge to social evolution.

The work in the clinics and classes should consist in studying the dynamic phases of human life, and should include an effort to get into the personality of the individual; it should not be based upon preconceived religiously accepted dogma. We shall then have to determine the adaptive tendencies of the individual, and his ability for education and re-education; we shall seek the readjustment of reaction, and the immunizing of morbidly sensitive conflicts through a better understanding or through suggestion. We shall also aim at environmental betterment, the adjustment of each individual to his psyche, and inversely to make the individual master of his soul.

Recent investigations have shown that certain mental trends or emotional complexes, which control the normal individual and largely influence our mental life, and which, during the ordinary activities of the day, are more or less lost sight of, lead to conflicting emotions and dilemmas even in normal individuals. Such perversions of normal processes are due to bad mental hygiene, and are easily acquired by the neurotic and hysteric. Consequently the large percentage of neurotics and hysterics with weak mental resistance and bad habits, should not be considered outcasts from society, and their conduct and lives should not be paralyzed either with regard to their own existence, or in their relation to their fellowmen.

We are all born with certain potentialities, positive and negative, social and antisocial. Whether these features become actualities depends upon the environment, and, just as many a talent has never been awakened, has never come to light for lack of proper stimuli, so many incipient vices may be overcome or diverted by proper training. We create a habit, and, by creating a good habit, the vice or evil habit can be overcome. Hence these neuropathic individuals and bad characters, may become, under proper stimuli and environment, more useful beings than people born without any neuropathic taint, but living under vicious or improper surroundings.

Every community ought to keep race hygiene records, or so-called anthropological records, where the individual would be able to find the sanitary history of his ancestry, and the necessary information regarding the advisability of his or her mating and propagating.

There are many more problems which will have to be met in the process of re-educating and purifying the race.

It is the finest and most imperative problem humanity has to accomplish. The task is a difficult, but not an impossible one, for there are no laws which can enforce the changes as long as the individual is not conscious of the necessity for them, and does not willingly co-operate. Before we can complete it, our mode of life and government will have to undergo great revolutionary changes; and immigration and our international relations will

have to undergo an alteration of form, and to assume a more ideal character. The movement toward the solution of these problems ought to become the religion of the present generation, and should be started as the *Race Hygiene Movement*.

THE VISCERAL LESIONS OF PURPURA HEMORRHAGICA AND ACUTE ARTICULAR RHEUMATISM.

By ANTHONY H. HARRIGAN, M.D.,

NEW YORK.

ASSOCIATE VISITING SURGEON (ACTING), FORDHAM HOSPITAL.

It is evident that in diseases the pathogenesis of which is vague, accurate clinical observation inevitably proves of aid, furnishing additional links in the chain of pathological reasoning. Surgeons with their opportunity for the study of living pathology are often able to furnish contributions to the elucidation of diseases, actually or supposedly in the realm of medicine. Occasionally the surgeon is led to a discovery of clinical or pathological interest through errors in diagnosis, a fact partly extenuating an operation needlessly performed.

The view that there is an intimate etiological and pathological relationship between purpura hemorrhagica and acute articular rheumatism is strongly sustained in the striking similarity in their clinical manifestations in certain types. This commingling of symptoms is the argument many clinicians use to demonstrate the relationship. This method of clinical analysis, while somewhat arbitrary, is extremely common in medicine, as it tends to simplify classification. When two diseases exist, similar in clinical manifestations, a somewhat hybrid picture is produced when the symptoms overlap. It is particularly in this twilight zone of pathology that interest is aroused. Attention is then focused on a lesion, or a group of symptoms which act as the connecting point between two apparently dissimilar symptom complexes. This relationship is well illustrated in acute articular rheumatism and the various forms of purpura.

The inflammatory reaction of the joints is common to both diseases. Though the arthritic symptoms may be transient or persistent, they occur nevertheless with sufficient frequency and definiteness to establish clearly a common causal relation. Much credit is due to Osler for calling attention to and emphasizing the importance of this clinical combination. His observations, the first to focus the attention of clinicians on this important and interesting topic, are embodied in a series of papers in which he successively developed his theme so as to include ultimately within the compass of these clinical associations such congeners of purpura as erythema multiforme, erythema nodosum, purpura simplex, peliosis rheumatica, etc.

One phase of this subject, of active interest and practical importance to the surgeon, is the occurrence of acute abdominal symptoms commonly called gastrointestinal crises. Osler laid considerable stress upon the value in the differential diagnosis. Since the publication of his original contributions, the literature has increased extensively,

until at present there are many case reports illustrating the diagnostic pitfalls.

In purpura hemorrhagica a gastrointestinal crisis may dominate the clinical picture. Under these circumstances, with abdominal pain as the paramount symptom, it is not astonishing that erroneous diagnoses are made. A common error is to diagnose acute appendicitis. This is particularly liable to happen during the initial stage of the disease, before the full development of the cutaneous eruption. Naturally, it is the location and severity of the abdominal symptoms which cause the error.

Though this diagnostic accident is not infrequent, many surgeons having published and recorded illustrative cases, there exists but relatively scanty and incomplete description of the visceral and peritoneal lesions found at the operation. It is somewhat strange that the lesions have not been accurately recorded, for any contribution, no matter how minute, must eventually be of value in a disease so vaguely understood.

The following case came under my care. The history is as follows:

M. G., girl, aged 13 years; admitted March 21, 1917; discharged April 18, 1917. Family history negative. Previous history, measles; does not recall any other serious illness. Appetite fair, bowels regular; no urinary trouble; weight about the same. Present illness began seven days ago. The patient began to complain of pain in the right lumbar region. She did not feel well; became tired on slight exertion. During this time the headache to which she is accustomed had become more severe. The pain gradually localized itself in the right lower quadrant, and the day before admission she vomited. Two days before admission she had to go to bed; shortly after this the knees, wrists and ankles began to swell, edematous. There was considerable stiffness, but no pain. General appearance, a poorly nourished and developed anemic-looking girl of 13 years. She is dull, listless, slightly stuporous. Slight photophobia. Pupils equal and regular, react to light and accommodation. Teeth in poor condition, tongue coated deeply, throat somewhat injected. No visible or palpable enlargements in the neck. Thin walled chest with fair resonance; no adventitious sounds elicited. Apex of heart in normal position; rhythm regular. There is a soft blowing systolic murmur at the apex. The second aortic is markedly accentuated. No marked rigidity or distention of abdomen; some generalized tenderness, particularly evidenced in the right lower quadrant. Tenderness over McBurney's point; palpation gives the sensation of an oval-shaped body in the right iliac fossa; percussion negative. Opinion was divided as to the diagnosis. Acute rheumatism, appendicitis, and typhoid fever were mentioned. Operation was decided upon in view of the extreme McBurney tenderness. Liver, spleen, and kidney not palpable. There are a few red spots resembling rose spots on abdomen. Genitals not examined. Extremities poorly developed. Both knees and both elbows are slightly swollen, stiff, but painless. There are a few macular red spots with small blebs about the involved joints and about both ankles; left leg somewhat spastic. Knee jerks present. Lymph nodes not enlarged. Temperature, 100°; pulse, 108; respiration, 20. Urinalysis: Clear, amber, acid, 1030, albumin trace, sugar negative, marked indican, acetone negative; numerous red blood cells, few white blood cells, occasional finely granular cast, large amount of squamous epithelium urates.

Operation on March 22, 1917. Ether narcosis. Palpation under ether gave a distinct gurgling sensation. Right rectus incision. Transverse colon dark (lead) color; cecum delivered; appendix dark color. No signs of acute suppurative inflammation. Terminal ileum distended, dark red, thickened. Few hemorrhagic areas on surface. Ileum 3 ft. above was normal. Meckel's diverticulum seen, showing same features seen on in-

flamed ileum; mesenteric glands enlarged and swollen, brownish red in color (looks like lesion of typhoid fever). Several ounces of clear fluid in pelvis welled up through incision. Closed without drainage.

Patient recovered from the operation without any untoward symptoms. Five days following the operation the right wrist joint became swollen. The spasticity disappeared from the legs and was followed by the appearance of numerous well-defined purpuric spots over each ankle. They were well marked, particularly on the inner side. They were purple in color, did not disappear on pressure, and extended 3 in. above the ankle. Temperature is running low. Blood culture is negative on March 27, 1917. Widal negative for 24, 48, and 72 hours. Sodium bicarbonate gr. x, and sodium salicylate, gr. x, were given three times a day. The ankles were painted with oil of wintergreen. Discharged cured on April 18.

From a careful perusal of the description of the symptoms it is evident that the correct diagnosis was purpura hemorrhagica. The misleading abdominal symptoms, in the light of the ultimate diagnosis, were those of a severe gastrointestinal crisis. Their abrupt onset and rapidly increasing intensity dominated the clinical picture and induced the abdominal exploration. It was only when the eruption appeared that the correct diagnosis was made.

Though the history of this patient is of interest in differential diagnosis, I believe that it presents a matter of cardinal importance concerning the visceral pathology of purpura hemorrhagica. I refer, specifically, to the alteration in the mesenteric lymph nodes. The pathological changes were unmistakable. In view of the fact that careful investigation failed to discern any other lesion, the assumption is warranted that the inflammation of the mesenteric lymph nodes was the cause of the abdominal pain, tenderness, and rigidity. That these nodes should be involved is readily understood, if one considers purpura hemorrhagica as an infection closely allied to rheumatic fever.

Without attempting to be dogmatic or arbitrary, I have seized upon this specific finding in the mesenteric lymph nodes as a connecting link between purpura hemorrhagica and acute articular rheumatism. By no means should one infer that it always occurs or that reasoning is perfect. What I wish to point out is that a gastrointestinal crisis may take place in both purpura hemorrhagica and acute articular rheumatism, and that the operative findings are identical.

The occurrence of abdominal pain in acute articular rheumatism is not mentioned in the usual detailing of the symptomatology. That pain may occur and project itself as the dominant symptom during the onset of the disease is proved by my personal experience and from a perusal of the literature.

In an historical survey of the subject of appendicitis one finds frequent reference and discussion regarding rheumatic appendicitis. Many writers have contended with dogmatic assurance that rheumatism is the most common cause of appendicitis. These statements are valueless because they are merely expressions of opinion unsupported by operation or post-mortem examination. From a reading of this phase of the literature of appendicitis, it appears that at one time every conceivable condition was adduced as the cause of appendicitis.

Moreover, the term rheumatism then possessed

vagueness and indefiniteness and lacked clinical precision. At present the effort is made, and correctly so, to limit its use to the specific infection associated with polyarthritides. Therefore, the older literature of so-called rheumatic appendicitis is worthless for the purpose of analysis.

The following case is reported to demonstrate the occurrence of gastrointestinal crises in rheumatism.

F. S., schoolboy, aged 14 years, admitted Aug. 6, 1913, discharged Aug. 24, 1913.

Family history, father died from heart failure one year ago; mother alive and well; brother in good health. Previous history, is of regular habits; had mumps; rheumatism two years ago; bowels regular until present illness; regular mixed diet. Present illness began four days before admission with severe frontal headache and vague pain in the abdomen. Three days ago complained of pain in head and abdomen; the pain at present is in the right iliac region, headache since illness began; felt feverish since the day before admission; no chill, sweat, or nosebleed; bowels constipated; no nausea or vomiting. General appearance, well developed male of 14 years; fairly well nourished; anxious expression. Pupils equal; circular; react to light and accommodation. Mucous membrane healthy in appearance. Tongue is coated white, no fissures or tremor. Distinct disagreeable musty odor to breath; teeth in very poor condition, decayed on margins of gums; tonsils normal in size; entire pharynx somewhat injected. There is a marked cardiac impulse in the fifth interspace on the mamillary line; marked impulse on palpation; on percussion, the heart is enlarged slightly downward to the left; auscultation gives a very loud blowing murmur systolic in time, heard best at sixth rib, one inch to the left of the nipple line; it is transmitted to the axillary region upward and to the right. Arteries, walls soft, marked carotid impulse. Pulse regular, full, and bounding; lungs, no adventitious sounds. Abdomen scaphoid in shape; no visible or palpable mass; no irregularity; no rigidity; not sensitive on palpation. Spleen palpable, extending two fingers below ribs. Skin warm, moist, no eruptions. Complaints of tenderness on right knee and left ankle when palpated. Muscles negative. Lymph nodes palpable on anterior cervical chain. Reflexes normal. Sexual organs apparently normal. Temperature 104°, pulse 100, respiration 28. Urine examination, clear; color, auburn; specific gravity, 1.012; reaction, acid; indican, moderate fat; no clots; casts, occasional granular (fine); crystals; urates. Blood examination, leucocytes, 14,000; polymorphonuclears, 80 per cent.; lymphocytes, 18 per cent.; mononuclears, 2 per cent. Widal examination, 1-20 for thirty-five minutes, negative. Prepared for emergency abdominal operation; diagnosis; acute appendicitis.

Operation, Aug. 6, 1913. Ether narcosis. The abdomen was opened through an intramuscular incision. The appendix was negative. The mesenteric lymph nodes were generally swollen, soft, red in color. Appendectomy. The abdomen was closed with drainage.

Aug. 7, 1913. Patient complains of pain in entire head; did not sleep well, "pillows too hard"; pain in knees and left ankle, no visible abnormalities seen on same; temperature 102°, pulse 82, respiration 26; Widal taken. Complaints of small enlargement on left side of tongue and pain in right anterior cervical region on palpation.

Aug. 10, 1913. The patient complained of severe pain in the knee joints, which became swollen, hot, red, and tender. Transferred to the Medical Ward. The diagnosis of acute articular rheumatism was evident. Salicylates were generously administered with complete subsidence of the joint symptoms. Primary union. Patient discharged in good condition.

The cardinal fact in the recital of the history is the occurrence of the acute abdominal symptoms. Their prominence and sharpness accentuated the clinical record and furnished the indication for operation. To one accustomed to think of acute articular rheumatism in the terms of the stereo-

typed description, the occurrence of abdominal symptoms not only appears with a startling freshness, but the idea of an abdominal operation seems bizarre. A finer analysis, however, rapidly dispels the confusion. With the well established association of purpura and rheumatism kept clearly in mind, the analogy between the abdominal symptoms is rapidly seen and accepted. The similarity is exceedingly close. Reasoning from analogy, it would seem logical to assume that the patient suffered from a gastrointestinal crisis, absolutely comparable to that seen in purpura. This view is not only strongly strengthened, but, in fact, receives practical confirmation from the pathological findings in the mesenteric lymph nodes. In each instance these were unquestionably the cause of the symptoms. Moreover, they were identical macroscopically. In fact, the changes in the nodes were sufficiently conspicuous and characteristic to constitute to my mind strong evidence as to the unity of the diseases.

The mesenteric lymph nodes play, occasionally, an important part in the causation and production of acute abdominal symptoms. There is a definite group of cases in which the symptoms of acute appendicitis are effectively mimicked. I have operated on a few of these patients. The appendix is usually normal; the mesenteric lymph nodes are distinctively enlarged, whitish in color, non-adherent, and the peritoneum is normal in color and texture. In the absence of microscopical evidence of inflammation or degeneration of the appendix, it is difficult to ascribe a cause. It is probable that the toxemia of intestinal stasis is a factor. As these patients usually recover without the slightest detriment to their physical condition, one is tempted to view the condition as purely physiological in origin. On the other hand, there is a form of tuberculosis of the lymph nodes, in the mesentery of the terminal ileum, that has exacerbations with fever, pain, tenderness over McBurney's point, rigidity, and leucocytosis. The symptoms of acute appendicitis are effectively simulated. I have operated in, perhaps, eight cases of this nature; in all the appendix was normal, save in one, where it was definitely tuberculous. The diagnosis is not only established from the characteristic appearance of the nodes, but the history often aids in furnishing confirmatory details as the history of an operation for tuberculous nodes elsewhere in the body.

The enlargement of the mesenteric lymph nodes in typhoid fever is entirely different from the two types of enlargement reported above—the innocent and the tuberculous. The nodes of typhoid fever are soft, swollen, and torrid red in color. The diagnosis is comparatively simple as proved by the subsequent evolution and course of typhoid fever. I have operated three times for abdominal pain supposed to be produced by acute appendicitis, only to find an innocent appendix associated with considerable swelling of the mesenteric lymph nodes. These three patients following operation showed the symptoms of typhoid fever verified by the positive Widal and blood culture. In other words, one is led to assume that the symptoms in these three cases, as well as the symptoms in the above-mentioned cases of tuberculous nodes, were produced through the swelling of the nodes.

The point which I wish to emphasize is the striking similarity, yes, the direct identity of the lesion in the mesenteric lymph nodes in purpura and rheumatism. The sameness of etiology or cause can be maintained with a considerable degree of reasonableness in view of the well established and generally admitted association of purpura hemorrhagica and rheumatism. In sum, there is a specific infection which not only produces arthritis and purpuric eruptions, but involves the mesenteric lymph nodes of the intestines.

An essential point to remember is that when the mesenteric lymph nodes are affected, abdominal pain may be the chief symptom. The surgeon should be acquainted with the clinical manifestations of articular rheumatism and purpura hemorrhagica; unless many of these cases are studied in detail and the symptoms analyzed, numerous mistakes will be made, in view of the striking similarity of the symptoms to acute appendicitis. Keeping the above point in mind, the surgeon should in the future, in obscure or doubtful cases of appendicitis, examine the skin with great care for purpuric spots, or inquire closely into the occurrence of arthritis or the existence of rheumatism, endocarditis, chorea, and tonsillitis.

391 WEST END AVENUE

Medicolegal Notes.

Damages for Unauthorized Autopsy.—The Minnesota Supreme Court holds that it is no defense to an action to recover damages caused by an autopsy performed on the body of the plaintiff's daughter without the consent of the next of kin, that the defendant, as the attending physician, was unable to ascertain the cause of death and performed the autopsy for that purpose so as to be able to give a certificate as required by law stating the cause of death.—*Woods v. Graham*, Minnesota Supreme Court, 167 N.W. 113.

Evidence as to Fracture of Skull.—In an action for personal injuries received in a railway accident the plaintiff testified that he received a severe blow on the back of his head which fractured his skull. His head was exhibited to the jury, showing a marked depression in the skull at the point where he located the injury. In connection with this he offered the testimony of experts, who stated that the skull had been fractured. To rebut that evidence the defendant produced testimony of an expert who had examined the plaintiff and who stated that the skull was not fractured. This expert also testified that the depression upon the plaintiff's skull was one sometimes found in the heads of normal people. As tending to corroborate that statement the defendant offered in evidence the x-ray pictures of two men whose heads showed similar depressions. This evidence was not admitted. This ruling was affirmed on appeal on the ground that a congenital malformation in the skull of one person is no evidence that an abnormal condition somewhat similar in the skull of another is not due to some postnatal cause. The very fact that such a condition is unusual indicates that it is an abnormal one. The relevancy of such testimony must be determined by the trial judge, and his rulings will not be disturbed except when it is made to appear that the complaining party has been deprived of a substantial benefit in the exclusion of the preferred testimony.—*Texas & P. R. Co. v. Williams*, Texas Court of Civil Appeals, 200 S. W. 1149.

Recovery for Mental Suffering.—The North Carolina Supreme Court holds that as all pain is mental and centers in the brain, it follows that as an element of damage for personal injury the injured party may recover for actual suffering of mind and body when they are the immediate and necessary consequences of the negligent injury.—*Hargis v. Knoxville Power Co.* (N. Car.) 94 S. E. 702.

Military Medicine.

THE ORGANIZATION OF THE MEDICAL PROFESSION FOR WAR.

PRESIDENTIAL ADDRESS.*

ARTHUR DEAN BEVAN, M.D.,

CHICAGO.

I FEEL greatly honored by the election to the position of President of the American Medical Association. I recognize not only the honor but also the responsibility of assuming the leadership of the organized medical profession of the country at this time. The war has made unusual and exacting demands on us. The government and the people are looking to us to furnish in this great emergency not only the necessary number of medical men for the Army and Navy, but also the highest degree of medical service and efficiency. This is proving to be a war not simply between well-organized armies but between efficiently organized nations. It is now clear that in order to win the war we must organize the entire nation in such a way that every man and every woman must become a useful part of a great and powerful national military machine. No part of such a great national organization is more important than the medical profession, and on this, the opening evening of this great war meeting of American physicians, it is my purpose to address you on the organization of the medical profession for war.

Organization of the Association.—There are in the United States more than 145,000 men and women licensed in the various States to practise medicine. Of these more than 81,000 are members of the American Medical Association, and more than 45,000 are Fellows. The American Medical Association is organized along the most democratic and representative lines. No profession in this or in any other country is more thoroughly and efficiently organized than the American Medical Association. The unit of the organization is the county medical society. It is the avowed purpose of the county society to receive into its membership all reputable practitioners who are legally qualified to practise medicine. The county medical society is a democratic organization. It is not, nor is it intended to be, a select and exclusive medical society. Its functions are educational and social. It exists for the purpose of using the united efforts of the physicians of that county for the benefit of the people and for the education of its members. Any county society that is not democratic and representative is not fulfilling its proper function. By virtue of membership in the county society the physician becomes a member of his State medical society and of the national society—the American Medical Association.

During the first half century of its existence the American Medical Association was a rather loosely organized body. It was founded for the special purpose of elevating the standards of medical education and practice. Its ideals were high, and it accomplished a great deal of good. Not, however, until its reorganization in 1901 on broad democratic and

representative lines did it become in fact the organized medical profession of the country. The American Medical Association is not sectarian, but is broad enough to include in its membership all licensed physicians who honorably practise scientific medicine.

Activities of the Association.—Since its reorganization the American Medical Association has had a record of splendid achievement. It has succeeded in elevating the standards of medical education in this country, which had been uneven and unsatisfactory, to a position where they are as high as those in any other country. It has improved the character of medical instruction until we can now state without fear of contradiction that the medical student can obtain as thorough and complete an education here in America as anywhere in the world.

Moreover, the American Medical Association has accomplished much through its Council on Medical Education in cooperation with the *Journal*. Through these departments it has been of great service in creating a register of licensed practitioners. A register of medical students is now kept so that the association possesses a full record of the medical career of each licensed practitioner and medical student.

The American Medical Association and its constituent State medical associations have succeeded in securing improvements in the medical practice acts of most of our States protecting the people against ignorant and inefficient practitioners and securing better public health service.

The American Medical Association has through its Council on Pharmacy and Chemistry done outstanding pioneer work against the unscientific and unnecessary use of drugs and against the prescribing of secret formulas and "quack" medicines. It has done more than any other medical organization to place drug therapy on a sound and scientific basis.

The *Journal of the American Medical Association* has become the largest and most influential medical periodical in the world. It has a circulation of more than 65,000 copies, and in the best sense it is the instrument that keeps the profession in touch with the affairs of the association, with scientific medicine, and through well-prepared abstracts with the current medical literature of the world.

It is now more important than ever that these admirable activities of the association should be continued and amplified, and that steps should be taken to meet the new problems that will confront the association after the war. These will undoubtedly include the stimulation of medical research, the development of an adequate American medical literature, the creation of post-graduate medical facilities not only for our own medical men, but also for the medical men from other countries, who will find here in our great democracy a welcome and opportunities in medical instruction and medical research second to none. But these things can and must wait on the one great problem that confronts us now, *the winning of the war*.

Demands Made by the War.—The problem that confronts the country in this war, as far as the development of the medical departments of the United States Army, Navy and Public Health Service are concerned, can briefly be stated in this way:

*Delivered before the American Medical Association at the Sixty-ninth Annual Session, Chicago, June 11, 1918; courtesy of the *Journal of the American Medical Association*.

If we raise an army of 3,000,000 men, 10 per cent. of this number will be in the medical department; that is, 300,000 officers and men, and of these at least 25,000 must be qualified physicians and surgeons. If we raise an army of 5,000,000 men, the medical department will contain 500,000 officers and men, and it will be necessary to have between 35,000 and 40,000 qualified medical men. At present there are more than 200,000 men authorized in the Medical Department of the Army. Of these, somewhere from 20,000 to 25,000 will be medical officers, and the balance enlisted men and nurses. If we create a navy of 500,000 we shall need 3,500 medical men. If we create a navy of a million, which is probable, we shall need 7,000 medical men. The need of the Public Health Service, although more modest, will be considerable, and must be met. No one can prophesy the extent or duration of the war, but we can say with certainty that it is the purpose of the American people to create and maintain the largest and most efficient navy in the world and to organize and train and equip an army large enough to win the war.

Who Represents the Medical Profession?—The efficient organization of the medical profession of this country for war is being splendidly accomplished by the cooperation between the medical departments of the Army and Navy and the organized profession, the American Medical Association. It has been unfortunate that a medical advisory committee which is not in any way representative or democratic, and which has no proper function in the efficient organization of the medical profession for war, should have been called into existence. A small coterie of specialists, of gynecologists, and surgeons, no matter how eminent or how successful they may have been as promoters and exploiters of special medical societies, can in no way in this great emergency and in this great democracy represent the medical profession.

Response of the Profession.—At the outbreak of the war the American Medical Association offered to the United States Government its entire organization and machinery to assist in the enormous expansion that became necessary. Through the officers of the county societies, the State societies, and particularly through the columns of the *Journal*, the needs of the Government were placed before the organized profession of the country, and they responded splendidly to the call. So far 25,000 have gone into the medical departments of the Army and Navy. No other profession or calling has responded more promptly to the needs of the country than the medical profession. The great bulk of the medical men who have gone into the Government services were members of the American Medical Association.

The demands made on the medical profession by the war are so great that it is evident that in order to secure the necessary number of medical men for the Government, and at the same time prevent hardships in some communities and institutions, it is necessary to organize the entire profession of the country in a systematic way. It therefore became necessary for the American Medical Association, acting with the Surgeon-General's Office, to take a census of the available medical men in the United States, in each State, in each county, in each

medical school, and in each hospital, and to attempt to secure from each one of these different units at least 20 per cent. of the medical men. This plan will enable the Government to secure the necessary number of medical officers for an army of 5,000,000 men or more, and a navy of 1,000,000, without any great hardship to any community or to any institution. It is evident that a plan of this kind is absolutely essential, and it is the purpose of the American Medical Association, through its county and State societies and its national organization, to create such a systematic classification and secure the adoption of this plan. Such a plan means a voluntary draft of the medical profession by the profession itself. The medical profession will supply the men needed by the Government. No conscription, no compulsion, will be required.

The Honor Roll.—The survey has been completed, and was published in the *Journal*, June 1. It gives the honor roll of the men who have already gone into the service from each county and State society. It gives the number of men under 45 and under 55 years of age in each county, and the percentage of men who have volunteered. Up to this date about 15 per cent. of the total number of men have volunteered. The Surgeon-General of the Army has called for 5,000 more medical officers, and the Surgeon-General of the Navy needs about 2,000. It becomes necessary for us to raise the total number of medical officers this year to about 30,000, which means nearly 22 per cent. of the medical men of the country.

As President of the association, I desire to call the serious consideration of each county medical society to the fact that in order to do its duty it should furnish at least 20 per cent. of its members for military service. This situation should be met fully and promptly by each county medical society. In order to prevent hardships to communities due to lack of medical service, and in order to prevent the crippling of medical schools and hospitals, no community and no institution, unless it is clearly over-supplied, should be allowed to furnish more than 50 per cent. of its medical men. As far as possible, the quota from each county should be filled by men under 45 years of age. If this is not possible, men up to 55 will be taken. As fast as each county fills its quota of 20 per cent.—and this should be done by each county within the next few months—the secretary of the county medical society should notify the secretary of the State medical association and the secretary of the American Medical Association of that fact.

The Supply of Medical Men.—Profiting by the experience of the great nations that entered the war in 1914, the medical profession of the country, and the Government, have very wisely taken steps to prevent the disruption of our medical schools, and I am glad to say that our National Government adopted the suggestion made by the Surgeon-General to allow medical students to be commissioned in the enlisted Medical Reserve Corps and have them detailed to complete their medical education and to serve a year in a hospital as internes before they are called into active service. This was to apply to the men who have already studied medicine in the medical school proper for one year. In order to insure the further supply of medical students to

meet the demands of a great and prolonged war, the effort is being made to have this apply also to the men who are taking their premedical work in universities. It is necessary to have these men continue their medical studies in order to insure the continued supply and the necessary number of medical men.

The United States is the only great reservoir of medical men in the world. The medical professions of Great Britain and France, of Italy and Belgium, and this is probably more true of enemy countries, have been well-nigh exhausted by this war. They delayed making plans for a continued supply, their medical schools became disrupted, and they are already suffering for medical men in their armies and in their civil life. Major Horace B. Arnold, chairman of the Council on Medical Education, who is on active duty in the Surgeon-General's Office, looking after the problem on medical education for General Gorgas, has this matter now under consideration, and it is to be hoped that he will succeed in securing rulings that will enable our premedical students to continue their medical courses. If the need for medical men becomes very great we can adopt a continuous session, and graduate men in three years. The senior students in the medical schools should have special courses in military surgery. I would recommend that, if possible, one or two competent medical officers be assigned to each medical school for this purpose.

Expansion of the Medical Department.—The enormous problem that was presented to the Surgeon-General's Office by the war may be realized in a striking way by the statement that the development of an adequate medical department for 3,000,000 men means that less than 2 per cent. of such a department is represented by the men in the service at the time of the outbreak of the war—that more than 98 per cent. of the men must be taken from civil life, and must be given the necessary military training to fit them for active duty in the field. This enormous problem is being adequately and splendidly met. A small medical department which existed before the war has formed the leaven necessary to change a great body of physicians coming from civil life into efficient military surgeons and efficient hospital and ambulance units. Special training camps for medical men were formed at Fort Riley, Fort Benjamin Harrison and Fort Oglethorpe. Gradually the work done by these different camps is being concentrated at Fort Oglethorpe, where an enormous military medical university of 40,000 officers and men is being created. Here the enlisted men will receive their necessary training in small and large units, and the medical officers will receive their necessary military instruction and instruction in such medical work as will peculiarly fit them for their military duties.

General Gorgas.—Standing out prominently in the development of the great Medical Department of the Army is a great figure, the figure of Surgeon-General Gorgas, who in a very quiet way has demonstrated again the fact that he is one of the greatest organizers in sanitation and in military medicine and surgery. It is most fortunate that in this emergency work of the medical department it was found in such strong and capable hands. General Gorgas is one of the great assets of this country to-

day. The splendid work that he is doing he should continue to do throughout the war, and the organized profession of this country could do no greater service to the government than to make clear to the Washington authorities that they are unanimous in their support of Surgeon-General Gorgas, and regard him as the best man in the country for the head of the Medical Department of the Army.

General Gorgas has succeeded in surrounding himself with the strongest, most efficient men, and has shown great wisdom and judgment in placing specially qualified men at the heads of the many departments under his control. The men he has chosen from the regular corps as the heads of divisions are strong and efficient: it is only necessary to mention such men as Welch, Vaughan, Billings, Mayo, de Schweinitz and scores of others, who in civil life are the recognized leaders in their special field of work, recognized not only in this country but throughout the world.

We are equally fortunate in finding the Medical Department of the Navy in the efficient hands of Admiral Braisted, who has succeeded in meeting the great expansion made necessary by the war in the most satisfactory way.

The medical profession is also proud of the splendid service that has been rendered by the Public Health Service under the able leadership of Surgeon-General Blue.

Health During Mobilization.—The mobilization of this country for war is an enormous task. To create an army of from three to five million men or more, where before we had less than 100,000, and create a navy of from 500,000 to 1,000,000 is an undertaking that had never before been worked out by any country. It was necessary that this enormous mobilization should be done as rapidly as possible, and from the rapidity and the enormous size of the mobilization it was inevitable that the medical organization could not accomplish the impossible and secure at once ideal results. Yet when we compare the mobilization of the United States for war with other countries we find cause for congratulation. Up to the time of our mobilization the army of Japan had held the record for the lowest mortality of any country during mobilization, and the best care of its soldiers from a medical standpoint. In the Japanese mobilization there was a mortality of 20 per thousand. In our mobilization there has been a little less than 10 per thousand. In other words, the showing of our mobilization from the standpoint of mortality was twice as good as the record held by any country up to that time. There have been epidemics of contagious diseases, such as measles, mumps and meningitis, and the total number of cases occurring among 2,000,000 men has been somewhat startling; but when these facts are analyzed and it is found that the mortality in our army is less than the mortality in civil life of the same number of men of the same age, picked by insurance companies, we can realize what splendid results have been accomplished.

The people of this country, the mothers and fathers and wives, whose sons and husbands are in the Army and Navy, are entitled to know, and it will be a great comfort to them to know, that the health of these men is better looked out for than when they were in civil life, that the dangers that

they run from disease are less than when they were in civil life, and that when they are sick or wounded they will receive as good care, as high a class of medical and surgical service, as could possibly be obtained in civil life. This is true because our best men have gone into the medical service, and the government is providing the medical departments with every facility necessary to give our soldiers the best medical care.

The Venereal Problem.—Strikingly successful has been the handling of the venereal problem. A careful examination of the evidence shows that venereal disease is only about half as frequent in men after they enter the Army as in similar groups of individuals in civil life. Certainly no army has ever been mobilized which has been as clean morally and free from venereal disease as the present American Army. Associated with this fact and responsible in large part for the splendid showing made is the elimination in large part of drink from the Army. Certainly no army has ever been mobilized that has been as free from drinking as the American Army. It was fortunate that our mobilization occurred at a time when the amount of drinking in this country was rapidly diminishing, and at a time when most of our states were going on a prohibition basis. Special efforts have been made by the government in the way of laws that have been enacted for this purpose to prevent drinking in Army posts and in territory immediately contiguous to them. This leads me to a consideration of the problem of drinking and prohibition as a purely medical problem.

Necessity of Eliminating Drink.—As we analyze the facts in a scientific and medical way there can be no doubt of the injurious effects of alcoholic drinks on both the physical and the mental well-being of our population. There can be no doubt that the greatest single factor that we can control in the interests of the public health of the nation would be the elimination of alcoholic drink.

In the slow evolution of civilization, many great wrongs persisted for centuries because people had become so accustomed to them that they were accepted as matters of course. They became so entrenched that it required either centuries of education or a revolution to extirpate or right them. Great epidemics and plagues were accepted as inevitable and as visitations of God. Government by autocratic power and divine right without the consent of the governed has been tolerated. Slavery with its horrors was defended. The unequal rights of women went unquestioned. Among these great wrongs too long tolerated, none has done more injury to mankind than drink. Events now are moving rapidly in the convulsions of a world war. Women have demanded and will obtain, as they deserve the world over, their equal rights. The course of events is writing the death warrant of autocracy and rule by divine right; and science and education should eliminate not only the plagues and epidemics but also the curse of drink from the world.

I want to plead for the united action of the organized medical profession of this country to secure protection by law against the injury that drink is doing to our people, not as a political measure, but as the most important public health measure that could be secured. In this crisis when we and our allies are fighting not only for ourselves but also for human-

ity and civilization, we must organize the entire nation in the most efficient possible way, and this cannot be done without eliminating drink. Each member of the medical profession as an individual, each county medical society, each state medical society should take an active part in the propaganda against drink, and secure national prohibition, not years from now but now when it is so badly needed and will accomplish so much good, not only for our boys in khaki and in blue, but for the nation in arms. And when it has once been done away with, it could no more be resurrected after the war than could slavery.

The Nurses.—One of the serious problems now confronting us is the securing of the necessary number of women nurses for our Army and Navy hospitals. We shall need from 25,000 to 40,000 women nurses. These cannot be secured from the trained and registered nurses of the country and leave a sufficient number of nurses to care for our civilian population. It requires three years of training in times of peace to educate a nurse. But we must remember that in peace times it requires a four years' training at West Point and Annapolis to make an officer of the Army or Navy. In the emergency of this war we are developing splendid officers from well educated, capable men taken from civil life, by intensive short three months' courses in our officers' training camps. The same plan should be adopted in securing the necessary nurses.

There are thousands of well educated, capable young women in this country who are not only willing but are anxious to offer their services to the country. Nurses' training camps and training schools can be developed in our Army and Navy cantonments where, with an intensive three months' training, these young women can be developed into most useful war nurses, and meet the needs of the Government. The Surgeon-General of the Army has already taken steps to encourage these nurses' training schools.

Reconstruction and Reeducation.—Another great problem confronting us is the reconstruction and reeducation of our wounded coming back from the war. Our allies after four years of war, bringing with it hundreds of thousands of cripples, have demonstrated what great good can be accomplished by reconstruction and reeducation. The injured man is reeducated to do some useful work. He is not allowed to drift as a useless wreck, a burden to himself and the community. He is recalled to life by a process of training and reeducation that enables him to earn his livelihood, to occupy his mind and to make life—even with a handicapped body—worth living. Surgeon-General Gorgas has been fortunate in securing as the head of this important reconstruction work our own Dr., now Colonel, Frank Billings, who will have the earnest support of thousands of men and women throughout the country in making this work successful.

Drugs and Chemicals.—An organized effort should be made by the medical profession of the country to secure the creation and maintenance of industries for the production in this country of the necessary drugs and chemicals, surgical instruments and appliances, making this country inde-

pendent in productions of this kind from other countries of the world. The securing of such legislation by the national government as will protect by proper tariff these industries in the process of development is essential. With the 145,000 medical men in this country, with the population and wealth of this country, we are the largest market in the world for drugs, instruments and medical appliances. By proper legislation, industries could be developed so that these products could be made here as cheaply as anywhere in the world, in such quantities as not only to supply our own market but also to enable us to enter other markets and maintain commercially our position in the western hemisphere, especially in this country and in South America.

Health of the Civil Population.—One matter which the profession should not lose sight of in endeavoring to meet the great demand made by war is the health of our civil population. The importance of maintaining and increasing and making more effective a national Public Health Service with wide authority, of developing in each county and each State strong public health departments, cannot be questioned. We should demand such State and national organizations for public health and preventive medicine that will secure for our people in a much better way than at present the great possibilities of modern preventive medicine. The war makes this matter not less but more important.

One Hundred Per Cent. Loyalty.—In organizing the medical profession of this country for war there is one fundamental and basic condition that must be secured: We as a profession must go into this war not only efficient, but we must go into it 100 per cent. loyal, 100 per cent. American. We are at war with a barbarous and brutal autocracy. The American people did not want to enter the war. It was only after the Imperial German Government had murdered our people and destroyed our property and treated our repeated protests with contempt that we prepared to defend ourselves against Germany, as an individual must against a murderer, a highwayman, a thief. We are at war with Germany and Austria. The Germans and Austrians who have chosen to make this country their home must choose between the land of their birth and America, the land in which their children are born. The choice with most of them has not been difficult. They have chosen their new home, the birthplace of their children, and these men and women we accept gladly as loyal Americans. But there are a few who are disloyal and would give aid and comfort to the enemy, and these must be sought out and interned where they can do no harm. It is the duty of every medical man and each county medical society to assist the government in securing the arrest and internment of every disloyal member of the medical profession.

There are in this country some German medical societies, and attention of the government authorities should be called to these. They should be disbanded at once. We should not permit, now, or in the future, in this country any organizations that further German propaganda. The world has had its lesson with this monstrous thing.

The International Fellowship of Science.—The American medical profession as a whole is more familiar with Germany and the German and Austrian people than is any other class of our countrymen. Thousands of our medical men have studied abroad in the clinics and laboratories of Great Britain and France, of Germany and Austria, of Switzerland and Italy. No other class of people in the world has felt more fully the international brotherhood of science than have American medical men. They have regarded scientific knowledge and scientific discoveries as the property not of one nation but of the world. They have accepted the great discoveries, such as Jenner's of vaccination, the American discovery of anesthesia, the work of Pasteur the great Frenchman, the work of Lister the great Englishman, the work of Koch the great German, the German discovery of the roentgen ray, the French discovery of radium, the American discovery of the manner of transmission and means of preventing the spread of yellow fever and typhus. They have accepted these and rejoiced that these great discoveries belonged not to one nation or one people, but were contributions to the great international science of medicine. What effect has the war had on this international fellowship of science?

Our Attitude Toward the German Medical Profession.—I believe we owe it as a duty to ourselves and to the German medical profession to state clearly the feelings and position of the American medical profession toward them. We can never again hold out to them the right hand of the fellowship of science until the German people drive from power and punish as they deserve the brutal and barbarous autocratic government which is responsible for this war, and have created in Germany a government of the people, by the people, and for the people. No matter what doubt or confusion there may have been at the outbreak of the war as to the guilt of the German government, the responsibility is to-day fixed and definite. The refusal to attempt a peaceful settlement before hostilities began, the outrage of Belgium, the invasion of France, the breaking of all international law, the sinking of the *Lusitania*, the evidence and revelations of the long prepared and worldwide plot of Germany to dominate Europe and the world by force of arms, the evidence furnished by the German ambassador to England, Prince Lichnowsky, the deliberate attempt of the German government while we were still at peace with Germany to embroil us in war with Mexico and Japan, the murder of Edith Cavell, the use of poisonous gases, the bombing of unfortified towns and cities, the acquiescence in the massacre of the Armenians by their Turkish allies, have all written with the indelible pencil of truth the history of German guilt.

No matter what sophistries the German people may advance as excuses for these things and for their precipitating war on Belgium, France, England, and Russia, we know that these cannot apply to America. We know that there is not a shadow of excuse for their making war on the American people. It required repeated outrages to convince the American people that the German government

was a thing without honor, that we were face to face with a highly organized and efficient autocracy which recognizes no law but the law of the jungle, an autocracy and a people who would rob their neighbors of their fair fields and their factories, their iron mines and their oil wells, an autocracy and a people who combine the frightfulness and moralities of the Hun with science and efficiency of the twentieth century, an autocracy and a people that have been seized with the insane egotism that they are God's chosen instruments to civilize and "kultur" the world, not by education and science, but with the mailed fist and the sword.

To medical men who are accustomed to study diseased bodies and minds, this state of mind of the German government and the German people seems like the insanity of a whole nation. We medical men are familiar with a horrible disease, which begins with an initial lesion acquired in a debauch and which ends often in insanity with delusions of grandeur and magnificence. It would seem as though the German nation was suffering from such a disease, from such a form of insanity. It acquired its initial lesion in the rape and outrage of Denmark, of Austria, and of France in the decade between 1860 and 1870. The virus of conquest and domination has coursed through its veins for more than fifty years, and has produced now a diseased national mind with the delusions of egotism and grandeur that are responsible for this world's war.

When the German people waken from the nightmare of the war, they must realize the enormity of the crime they have committed under the spell of the medieval autocratic government that controlled them. They will realize that although they might retain with profit to themselves a province stolen from Denmark or Poland, France or Belgium, they can never dominate with force of arms with profit to themselves for any length of time great nations like Russia and France, England, Italy, Japan, and America. We are in this war, as our great President has said, "to make the world safe for democracy;" and whether it takes one year or ten years, we shall continue the war until the brutal and barbarous autocracy of Germany is destroyed. If the German people could have but a brief period of freedom from their war madness, let them ask themselves if the few miles of Belgium and France and the occupied provinces of stricken Russia can compensate them for making nine-tenths of the world their bitter enemy. And they should be made to know that this is not the enmity of a day, the enmity that will disappear with a peace that they hope to compel by force of arms, but that it is an enmity that will last, that will mean for Germany a complete severance of relations, social, commercial, and in every way from ourselves and our allies until Germany has purged itself of guilt, and asks humbly for a place among the nations in which the people rule. The medical profession of America sends this message to the medical profession of Germany.

Our Single Purpose as a Nation.—To the medical professions of Belgium and France, of England and Italy, of Russia and Greece, of Portugal, Roumania, China and Japan, of Brazil and the Central

American Republics, to our colleagues in Canada and Australia and New Zealand and South Africa, and to the other nations who in response to German outrages have joined in war against her, we send a message to hold fast and be of good cheer. We have been a peace loving people, we loathe war, we have done everything a nation could in honor do to avoid war, but our people have been murdered by the German government and the German people, and we protested and they murdered more, and we protested and they murdered more, and we have been forced to defend ourselves and our rights. We have not been a military nation. We have been unprepared for a great war. But we have absolute confidence in the ultimate success of our democratic form of government. We believe that it is not only the best form of government in peace, but that it can be made the most efficient and best organized form of government in a great war. Let us tell our medical colleagues in the nations who are now our allies that America with its more than hundred million free men and women is organizing itself into a great military machine, that all our people, that all our resources, that everything we have is being converted as fast as brains and energy and money can convert them into a weapon with which to win this war, which is now our war. Let us tell them to hold fast and be of good cheer, for America is coming.

America asks nothing for herself. She comes with a clear conscience, a sane national mind, a stout heart, and a strong arm. She comes with the single purpose of a united people, a hundred million strong, to punish the murderers of her people and to win this war for civilization and humanity.

Let us send from this meeting of the organized medical profession of America to our great leader in Washington a message, the message that wells up from every farm and factory, from every town and hamlet, the message that echoes and reechoes through our country, from the mountains through the valleys to the sea, the message that is sent by every man and woman of America when our government calls for their services in this war:

We hear the call of our country. We answer, we are here.

Hysterical Mutism and Deafness in Soldiers and Their Treatment.—Dr. Colin McDowal, writing in the *Journal of Mental Science* for January, 1918, says that the forms of treatment of mutism are endless in variety. McDowal's own treatment may be briefly described as follows: The patient is asked to take a long breath. He is then told to hold his breath; he fails, but very frequently insists that he succeeded. He is then given a cigarette, which he is asked to inhale, when the patient at once discovers that he is incapable of holding his breath. He learns possibly for the first time that his respiratory apparatus is at fault. Exercises to promote correct breathing are then undertaken. The most important point is to obtain a good volume of breath without hesitation on expiration. He is asked to blow out a match at increasing distances; then to breathe freely, trying to say "Ah!" at the same time; then to sigh

the sound "ow" and later the sound "ou." Three long breaths and three sighs together with the correct mouth formation produce the sentence "How are you?" Once deep breathing is established a sudden squeeze of the abdominal wall will produce phonation. The immediate effect will be a display of emotion. Tears are frequently the precursor of speech. As soon as a man can whisper faintly but sufficiently for others to hear McDowal brings in another patient or a nurse to show the patient that he can now be understood. The following day the same process is repeated, and, as a rule, the man will talk freely after the third day. The method of suddenly squeezing the abdominal wall has already been described in a French journal.

Deafness is also dealt with on simple, common sense lines. The patient is seated in a chair and holds a small mirror in his hand. McDowal stands behind a man and instructs him to look at McDowal's eyes reflected in the mirror. After a suitable interval, a sudden noise is made without any movement on McDowal's part. The patient will blink and the mirror will render him conscious that he has moved his eyelids. He is also conscious that the movement is a proof that he can hear. The whole performance is simplicity itself and it appeals to the man's common sense and he is convinced against his inclination in some cases. In both these simple methods the principal agents are common sense and re-education. Lip reading and the use of the deaf and dumb alphabet should never be allowed.

The After Care of the Disabled Soldier.—A. W. Mayo Robson, writing in the *Hospital*, March 9, 1918, on the after-care of the disabled soldier, says that the question bristled with difficulties. There are many cases of men who had been discharged from the army with conditions which are largely remediable by operation, which procedure, however, they decline. To give an example, the man who worked an elevator which he happened to use was noticed to have wrist drop. When told it could be cured by operation he said he did not propose to have it done, he was receiving a pension of 28 shillings a week, on which he could go along comfortably. These men should be made to understand that by getting cured they would not lose their pension and by undergoing the necessary treatment the total productive power of the nation would be much increased. For the tuberculous cases a considerable number of sanatoria would need to be erected and there would have to be special centers for neurasthenic cases and shell shock patients. These did not do well in command depots, they should be right away from the sound of and associations of war. Also in connection with the patients in the many orthopedic hospitals, workshops, and training centers were needed, as well as hospitals or asylums for incurable cases. Robson insisted on the need for properly qualified people to be placed in charge of these institutions; those having special knowledge of the treatments and the apparatus; and they should exercise increasing watchfulness. With very large numbers of war victims a very important function was that of reeducating them to a stage at which they could resume active work.

The orthopedic hospitals would have to be continued after the war to treat and restore stiff joints, fractures with shortening and nerve cases causing deformities. In cases in which stiffness was inevitable it was most important that the ankylosis should take place with the limb in its most useful position; gunshot injuries through the joints, followed by suppuration, generally were succeeded by ankylosis. In the case of the shoulder, for instance, the arm should be kept abducted at an angle of 50 degrees, with the elbow slightly in front of the body and away from it, so that when it was at right angles and the forearm was supinated, the palm of the hand was towards the face. This enabled the hand to be of service when the arm was removed as a whole from the scapula. With regard to the elbow joint, the position must be always influenced by the patient's calling. In most cases the best functional results were obtained when the angle between the humerus and the forearm was a little greater than a right angle. The forearm should be supinated so that the palm is directed slightly upwards.

If both elbows were ankylosed one should be at an angle of 110° and the other at 70°, so that the movements of one arm could supplement those of the other. All injuries of the wrist should be treated with the wrist dorsi flexed and with the fingers spread well out. In hip joint cases ankylosis if inevitable should be secured in the position of slight abduction, and the thigh extended and slightly rotated outward. Knee cases should be fully extended, care being taken to avoid hyperextension. In injuries of the ankle the foot should be kept at a right angle. Many cases were seen in which the toes had been allowed to drop. A valgoid position was specially to be avoided. One should never try to get a stiff joint moved rapidly and on no account should an anesthetic be given for the purpose of moving a stiff joint; this might ultimately lead to permanent damage of the joint. These joints required very careful handling. Massage should be carried out for a few days and if no reaction followed the arm could be moved a little from the splint, raised, and then replaced, being content with doing only a little each day. If no reaction followed the procedure might be carried out each day and the patient encouraged to lift it actively from the splint. When this could be done easily the splint could be bent a little each day, thus enabling further movements to be performed. The underlying principle was one of alternate slight movement and rest. Only reaction must be taken as an indication that further rest was needed. Where injuries involved tissues in the neighborhood of joints, resulting in suppuration, deep scarring, etc., stiff joints often resulted, and here also no attempt at breaking down should be made, even under an anesthetic. With regard to injuries occurring at a distance from joints, with inflammatory changes in muscles, no joint, which was not the seat of arthritis should ever be allowed to stiffen permanently. When a joint could be moved with disturbing the fragments of a fracture that should be practised one gentle movement in each direction every other day sufficed. In reference to stiff fingers all splints for dorsi flexion of the wrist, especially where frac-

tures or inflammatory changes occurred in the metacarpals and phalanges, should hold the fingers in the position they assume when grasping a ball, care being taken not to exceed the ordinary metacarpo-phalangeal range, as a stiffening in that posture was impracticable. Massage and passive movement should be very greatly practised, splints should not be applied to the fingers, except where they were the actual seat of fracture or active inflammatory changes. In all forearm fractures the hand should be kept supinated; it was often difficult to secure supination, splints should be removed from the upper extremity at the earliest practicable moment, and in the case of the lower limbs sufficient rest should be given before the patient walks, as the softening of the bones caused by the accident might result in bowing.

Increase in the Medical Department of the Army.—Surgeon General Gorgas, in an address delivered before the Faculty of New York University and Bellevue Hospital Medical College, on June 5, told of the needs of the Medical Department of the Army and of the great expansion of that branch of the service during the past year. He stated that fourteen months ago we had not more than 600 doctors in the war zone. Our present personnel for the Medical Department commissioned officers is in the neighborhood of 20,000 men. We have sent 1,500 to the British Army. The number of nurses has increased in proportion; there were 300 nurses on the other side about a year ago and there are now about 1,200. With the constantly increasing number of troops more and more doctors are needed in France. In speaking of the casualty list that came through General Gorgas expressed himself as both surprised and distressed that the losses were so great. While we have not lost two dozen commissioned officers of the fighting forces, among the medical officers the casualties have been in the neighborhood of eighty. The bombing of hospitals by the German ruffian airman accounts for many of these losses.

Returning Sick and Wounded.—During the week ended May 31, 184 sick and wounded soldiers of the American Expeditionary Forces were landed in this country and distributed to various army hospitals. A statement issued by the Navy Department indicates that there were between 300 and 400 sick and wounded soldiers being brought home by the President Lincoln when she was sunk by a German submarine. All of these men were saved.

Bombs Kill Many in Hospitals.—A cablegram from the British Army Headquarters in France, under date of June 2, reports that night raiding has done great damage in the hospital area and that there has been a large loss of life. Among the list of killed are medical officers, patients, nurses, and attendants. Some of the wards were entirely demolished. In one hospital the casualties were confined to the attendants. In another the operating theater, fortunately empty at the time, was wrecked and the officers' mess was destroyed. Between May 15 and June 1, the Germans bombed British hospitals in France seven times, the casualties numbering 991, distributed

as follows: Killed—Officers, 11; other ranks, 318; nursing sisters, 5; women's auxiliary corps, 8; civilians, 6. Wounded—Officers, 18; other ranks, 534; nursing sisters, 11; women's auxiliary corps, 7; civilians, 73.

Hospital Ship Sinks.—The hospital ship *Konigin Regentes*, having on board the British delegates to the Anglo-German war prisoners' conference at the Hague, struck a mine off the English coast on June 5. The passengers were saved by the hospital ship *Sindoro*.

Vanderbilt Estate for Convalescent Hospital.—Mr. and Mrs. W. K. Vanderbilt, Sr., have offered their estate, "Idle Hour," at Oakdale, L. I., to the American Red Cross to be used as a convalescent hospital for soldiers. It is estimated that the estate will accommodate 1,500 soldiers. The Red Cross have inspected the property but have not reached a decision as to whether or not they will accept the offer.

Guard Against Shortage of Surgical Supplies.—The War Industries Board has created a commodity section on medicines and surgical supplies, with Lieutenant-Colonel F. F. Simpson as its chief. The new section will deal largely with surgical supplies, instruments and dressings, with serums, and with other medical and hospital supplies. It will be coordinated with the Chemical Division and will deal with chemicals, as these enter into medical compounds and preparations. Thus far no actual or prospective shortages have come to the notice of the board in only a few instances as far as medicines are concerned, but in dealing with these the new section will round out the work of the Chemical Division and guard against any possible shortage in these lines.

Report on Work for Blind Soldiers.—In a recent report made to the Committee for Men Blinded in Battle, Miss Winifred Holt, the committee representative in France, states that three branches of the Lighthouse for the Blind are now assisting about 150 blind soldiers daily, and giving about 2,800 lessons monthly. In all, the three French Lighthouses have come in touch with about 3,500 blind or partially blind whom they have assisted directly or indirectly. During the year 1917 about 2,000 woolen wraps were made by the blind knitters in the Lighthouses and sold for the benefit of the work. As the recent drives on the western front are greatly increasing the demands that will be made on this work they make a strong appeal for funds.

Social Hygiene Program for War Camps.—Dr. George E. Vincent, president of the Rockefeller Foundation, announces that \$35,000 has been appropriated to make possible an adequate demonstration of the application of a program of social hygiene in a typical war camp community. The announcement states that, while plans have been worked out in all the communities, no carefully developed program has been worked up. In the proposed plan the medical departments of the Army and Navy, State and Federal Health Services, the Red Cross, the Training Camps Commission, the Y. M. C. A., and similar organizations, are to cooperate with the American Social Hygiene Committee in the demonstration, and more than \$135,000 is available for the work.

ANAPHYLAXIS AND IMMUNITY.

LIKE many other questions, that of anaphylaxis at present has become a most intricate problem, because of the many experimental and theoretical solutions put forward in recent years. Anaphylaxis is a stable state in the dog, rabbit, and hen, unstable in the guinea-pig. If, after having given one or several necessary preparatory injections in order to confer the anaphylactic state on any of these animals, one waits weeks or months before undertaking the test of anaphylaxis, positive results will ensue. If, on the other hand, a preparatory injection is given to a guinea-pig and a fortnight later an injection which gives rise to a reaction, the anaphylactic state disappears and cannot be made to return in this particular animal. Anaphylaxis is specific in both the dog and the guinea-pig, but not so in the rabbit. A dog or guinea-pig prepared by the injection of horse serum will develop a paroxysm of anaphylaxis only when horse serum is injected, and no accident will result from injecting egg albumin or any other inoffensive liquid in an unprepared animal.

If, on the other hand, a rabbit has been prepared with horse serum, accidents of anaphylactic reaction may be produced by injecting some fluid other than horse serum, such as a solution of pepsin or egg albumin.

The symptomatology of anaphylactic reaction very greatly differs in the dog and in the rabbit. The latter presents local cutaneous and subcutaneous accidents not manifest in the dog. The rabbit presents changes in the respiratory rhythm not met with in the dog; the rabbit presents a sero-anaphylactic cachexia from which the dog is free. The guinea-pig, like the dog, shows neither the cutaneous reactions nor the cachexia. The hen, like the rabbit, presents local reactions, but not of the same sort, and, like both the dog and guinea-pig, it does not become cachectic after an intravenous injection of a fluid which is toxic in the circumstances. Finally, the dog and guinea-pig offer a passive anaphylaxis, not usually present in the rabbit.

From all these data it would appear logical to assume that the symptomatology of the anaphylactic reaction will be of a particular nature in dif-

ferent animal species and that, consequently, it is risky to generalize too hastily and to apply it to man, without direct verification of the results obtained in animals.

The procedures employed to anaphylactize animals and those used for immunizing them against toxins being quite similar, if not absolutely identical, some writers have supposed that these were two successive manifestations of one and the same organic change, the anaphylaxis preceding the immunity. To back this notion the following data have been brought forward, particularly by Wolf. By injecting intravenously a dog with cobra's venom in a non-lethal dose, a drop in the blood pressure and incoagulability of the blood result. By repeating the same injection in dogs that had previously been given several subcutaneous injections of non-lethal doses of the venom, it was noted that the intravenous injection provoked the same accidents as in an unprepared animal, but the fall in the blood-pressure was exaggerated in degree and duration—a manifestation of anaphylaxis.

If, now, the number of preparatory injections had been considerably increased, and then an intravenous injection given, it was noted that it was inoffensive, for doses which previously resulted in accidents, as if the animal had been for a time anaphylactized for the cobra's venom, and was now immunized against this venom. Immunity had followed anaphylaxis.

Equivalent data may be observed in the case of sero-anaphylaxis. Horse serum is inoffensive when injected intravenously in an unprepared dog. A dog which has been previously given one or several subcutaneous injections of horse serum will be intoxicated by horse serum later on, and if given intravenously the blood-pressure will fall and the blood will become incoagulable.

If a dog is injected subcutaneously with horse serum once weekly for twenty to thirty weeks, an intravenous injection of the same serum will not produce any accident, so that following seric anaphylaxis a seric immunity has likewise taken place. Similar phenomena are observed in the guinea-pig.

It is as yet too soon to form a definite opinion of these data, and further experimental work is necessary, but it would seem quite logical to suppose that the two states of anaphylaxis and immunity are independent and correspond to two equally stable organic changes.

SELF-PURIFICATION OF STREAMS.

EXCEPT in a few instances, the pollution of the waterways by inorganic matter from industrial plants has been banned by the courts of the several States, but it is the nature of a stream to suffer some degree of pollution, for no community can well live on the shores of a stream without polluting it. From the sanitary standpoint the question is the amount of permissible pollution in a stream before it becomes inimical to the animal life within it, or to the community drinking it, or before it becomes a

positive nuisance to those who must reside on its shores. From the narrower sanitary viewpoint the question of permissible stream pollution depends upon the amount and the kind of pathogenic organisms thrown into it, usually within the organic matter that forms the means of pollution. In communities that have to drink of this water the question of stream pollution with human excreta is a vital one, unless either the excreta are properly treated before entry into the stream or the water is treated before consumption. In a city situated as is New York the self-pollution of its water supply has no bearing, but the tidal waters can become so polluted with organic matters as to make the cultivation of sea foods dangerous, to make bathing in the waters objectionable, and the like. A small amount of stream pollution is rendered harmless by dilution, by sedimentation, and by the low resistance of the pathogenic organisms. It is perhaps for these reasons that typhoid infections in epidemic proportions are the result of only the grossest kind of pollution. Most of the organic matter in streams is taken care of by oxidation, just as it would be in the air. The reduction of such organic matter in streams is essentially biochemical. The oxidizable matter is brought in contact with the oxygen dissolved in the water and with the oxidizing bacteria, and the question of stream pollution depends mainly upon the amount of available oxygen present in the stream for this purpose. As the available oxygen of the water is consumed in this oxidization process, oxygen from the air re-enters the water in proportion as it is used up. The greater the initial amount of oxygen dissolved in a water the greater is the capacity of that particular water for free oxygen, taken from the air.

But the rate of re-aeration of water from the supply in the air depends not only upon its capacity but also and particularly upon the amount of agitation to which the stream is subjected. Indeed, as regards the self-purification of polluted streams it is the rate of agitation-aeration that is the important element. But the rate of re-aeration of a stream, independent of agitation, depends upon the vertical distribution of the oxygen concentration in that water (Phelps, Public Health Reports, No. 214). The saturation by absorption of oxygen from the atmosphere is naturally highest at the surface, in quiet waters, and ranges to the initial concentration at the lowest point. But sooner or later the diffusion of the oxygen becomes equal, and the oxygen concentration comes to a condition of equilibrium at all points. When the average oxygen concentration for this water is established, further diffusion of oxygen is slow or ceases altogether. But agitation of the water causes greater absorption and re-establishes diffusion, until an equilibrium is established at a higher oxygen concentration. In deep tide waters, such as in New York harbor, there is little actual agitation, and the only new oxygen is brought in from the ocean with each new tide. The amount of re-aeration in these waters is small and consequently the amount of pollution they can stand is slight. The initial

content of oxygen of these waters is large, but there is not sufficient re-aeration to replenish it. In rivers of much shallower constitution, on the other hand, the initial oxygen concentration is small, but because of the flux the amount of re-aeration is large; and the amount of pollution they can take care of is accordingly rather high. The estimation of the amount of initial oxygen concentration, re-aeration, etc., of a stream subject to pollution can be determined by laboratory methods. From the known constant velocity of reaction are determined changes in the amount and concentration of the reacting substance—the organic matter in the polluted stream. The aim of these determinations is to find the limit of capacity for self-purification of any stream under investigation.

FOOD AND HARD WORK.

UP to the present time, in this country, lack of food has not been obviously perceptible. True it is that prices have advanced which, presumably, is *prima facie* evidence of a diminishing supply, but again may not be, and as a matter of fact is not, the whole cause of the abnormal prices. At any rate, conditions as regards food are very far removed from those which prevail in Europe and it can be stated without hesitation that we have scarcely felt the pinch of war, and in comparison with Europe our troubles have been merely annoyances. However, this is not to say that the era of plenty in America will continue indefinitely. This country must not only feed its own inhabitants, but must greatly aid in feeding its allies. Therefore, it is well to be prepared for anything that may happen, one of which happenings is likely to be a scarcity of food or, at any rate, not that abundance to which Americans have become accustomed. Food readjustment in Great Britain has been no easy task. The Briton has been a somewhat large meat eater, and reduction of his meat ration has gone considerably against the grain. The same thing occurred in Germany, with, up to a certain limit, it is said, good results. In Great Britain the present diet has brought about a loss of weight in many people and has given rise to some apprehension.

Dr. Robert Hutchison discussed the medical aspects of food recently at a meeting of the West London Medico-Chirurgical Society. According to Hutchison such loss of weight was not progressive and could be reasonably explained from the standpoint of fundamental metabolism. He gave it as his opinion that a loss of 10 per cent. of normal body-weight was not harmful and might be beneficial. However, he pointed out that under such conditions unnecessary exercise should be avoided. The advice is excellent but in Great Britain nearly all who approach the able bodied standard have to work hard, which means taking a great deal of exercise and in consequence they must eat sufficient food to make up for waste and to supply the energy necessary to enable them to undergo the stress and strain of hard and prolonged labor. The protein of meat must be replaced by the protein of vege-

tables, potatoes, beans and so on. There are some diseases in which this change of protein-containing food is distinctly beneficial. As for fat, there are some who think that fat is not absolutely essential for the healthy adult, but can be replaced by carbohydrates. This is a matter which is still *sub judice* and in any event children should have fat. Again with regard to milk, there are those who hold that after infancy milk is not an essential food. Dr. Harry Campbell, for example, maintains that an adult needs no milk and that the best use to which milk can be put is to convert it into cheese, one of the most wholesome and nutritious of foods.

It goes without saying that persons engaged in strenuous toil, men or women, need and must have, if their output is to be large and their work efficient, a sufficiency of nourishing food. The greater the wear and tear of the muscles involved by hard work the greater the need for an abundance of nutritious food. It means then that the calculation of a scale of rations must be based upon the character of the work, and therefore the needs of the individual. Supplementary rations have been granted in Great Britain to those engaged in heavy industrial or agricultural work. Medical men, however, who are as a class notoriously hard workers and who generally speaking take a great deal of exercise are not included as participants in the supplementary rations. Women will share the same extra allowance of food as the men provided that their work is as strenuous. America can doubtless learn some useful lessons in connection with the food problem from Europe and perhaps especially from Great Britain.

SURGEON GENERAL GORGAS AT THE AGE OF RETIREMENT.

SURGEON GENERAL GORGAS will be sixty-four years old in October next and will therefore have reached the statutory age of retirement. Ordinarily an officer is retired automatically at this age, but fortunately the President has the power to abrogate this rule and retain any man in active service if he thinks it for the good of the country to do so. A number of petitions and individual requests have been presented to the President, asking that the country be not deprived of General Gorgas's services during the continuance of the war, and it would be deplorable if the will of the medical profession thus expressed were ignored.

There are, of course, many other men in the medical corps of the army who could fill the Surgeon General's place acceptably in time of peace. But this is war time, and others, able as they may be, have not had General Gorgas's opportunity to prove their capability. The opportunity came to him in Havana and he demonstrated his ability to meet it; it came to him again in Panama, and again he showed what he could do in the combat with disease; finally it came to him fourteen months ago, and the enormous expansion of the medical department, its increase in numbers and the tre-

mendous widening of its activities, is his response to the new demand. The medical profession of the country has, of course, helped him by its offer of services, and by its readiness to advise when asked—and he has freely asked advice in many cases where a smaller man would have felt himself fully able to act on his own responsibility—but the guiding mind has been the Surgeon General's and the state of preparedness in which the medical department of the army now finds itself bears further witness to his genius for organization.

President Wilson knows all this and there can be not the shadow of a doubt that General Gorgas will be kept at the helm, but all the same it may be well to assure the President that the expert judgment of the medical profession will acclaim the announcement that Gorgas must stay. It would be a graceful thing, too, if Congress would at the same time show its appreciation of what the Surgeon General has already done by strengthening his hands and passing the Owen-Dyer bill to increase the efficiency of the Army Medical Corps.

OCCUPATION AND MORTALITY.

THERE is a distinct and, in fact, an intimate relationship between occupation, illness, and mortality. Some trades are much more dangerous to health than others, and it is both valuable and interesting to compute as far as is possible mortality rates or to make comparisons of the mortality of the different occupations. In an article in reprint No. 400 from the Public Health Reports, Drs. Shirley Wilmotte Wynne and William H. Guilfooy conclude as follows: Their study would seem to point to the fact that mortality of the respiratory diseases is highest in those occupations which are carried on in crowded and poorly ventilated offices or shops, particularly the mortality of clerks, bookkeepers, office assistants, compositors, and printers. The low mortality of garment workers from pulmonary tuberculosis and pneumonia may be explained by a racial immunity to these diseases, and, moreover, in New York, a large number of persons engaged in the manufacture of clothing pursue their occupation in their own homes. There would seem to be ground for the belief that there is a relation between cancer and occupation, seeing that the mortality of this disease is uniformly lower in the strenuous occupations and higher in the sedentary ones, thus adding one more argument in support of the rapidly growing belief that cancer is a constitutional disease and no more local than is typhoid fever or tuberculosis. Investigations appear to show that there is an unduly high mortality from heart and Bright's disease among cigar-makers and tobacco workers, and also among garment workers which cannot be entirely explained by the advanced age of the workers in these occupations. Alcohol seems, as would be expected, to be an important hazard among saloonkeepers and bartenders and teamsters. Lobar pneumonia appears to be a hazard in two classes of occupation: first, those in which the workers are grouped together in shops and offices; secondly, in those occupations where the workers are alternately exposed

to high and low temperatures. In every occupation a small percentage of the workers commit suicide, but only among cigarmakers and saloonkeepers does the percentage rise above 4. In every occupation the percentages of death due to this cause are highest among those in the earlier ages. Accidents form a very serious hazard in those occupations where the liability to accidental violence is greatest. According to the authors, the administrative measures suggested by this study are, first, a crusade against pulmonary tuberculosis and the respiratory diseases among clerks, compositors, and similar groups, and a more extensive study of the causes of the high mortality from pulmonary tuberculosis among teamsters and drivers; secondly, a widespread effort to control the incidence of heart disease among garment workers and cigarmakers; third, a campaign against the use of alcohol. Apparently the occupational poisonings, as, for example, chronic lead poisoning, arsenic poisoning, etc., are an almost negligible factor in causing mortality among the workers of New York. The study of the relationship between occupation, sickness, and mortality has brought out some valuable data, and there is little doubt if investigations were conducted on a more systematized basis and on a wider scale that the results would be still more valuable.

News of the Week.

Free Antityphoid Inoculation for All.—Secretary McAdoo has directed that the United States Public Health Service give antityphoid inoculations without charge to all who apply to any of its hospitals or field offices. Many of these offices are in zones surrounding the military cantonments of this country. Emphasis is placed on the fact that the prevention of typhoid fever in these zones is one of the greatest steps in preventing the interchange of the disease between the military and civil populations. In Little Rock, Ark., more than 15,000 have been inoculated against typhoid fever by the Public Health Service. Applications may be made in person to any United States Marine Hospital, to any field office of the Public Health Service, or to the United States Hygienic Laboratory, Washington, D. C. Information as to the nearest place where an inoculation can be furnished will be given on application to the Public Health Service, Washington, D. C. The Public Health Service is making every effort, especially in the vicinity of the camps, to improve the means of disposing of human excreta, through both education and demonstrations. The States and localities are cooperating in the work and in a number of instances have appropriated money to be spent by the Public Health Service for demonstrations in rural sanitation in localities where an equal amount has been spent by the State or local authorities. For this purpose the States and localities have appropriated \$70,000 during the present fiscal year.

Smith College to Train Workers for Shell Shock Cases.—The National Committee for Mental Hygiene announces the establishment of an emergency war course at Smith College, Northampton, Mass., for the purpose of preparing workers to assist in the reclaiming of soldiers suffering from

nervous and mental diseases, including war neuroses and so-called shell shock. The course will cover eight months and will be open to college graduates and other young women who have an equivalent technical training. The academic instruction will be given at Smith College from July 8 to August 31, to be followed by six months' practice work to be given at various centers where there are opportunities for social work with psychiatric cases under the direction of trained social workers. The course will be conducted by Smith College and by the Boston Psychopathic Hospital under the auspices of the National Committee for Mental Hygiene, through a sub-committee composed of Dr. E. E. Southard of Boston, chairman; Dr. William L. Russell and Dr. L. Pierce Clark of New York, Dr. Walter E. Fernald of Waverley, Mass., and William A. Neilson, Ph.D., president of Smith College. Miss Mary C. Jarrett, chief of Social Service at the Boston Psychopathic Hospital, will be the director of the course.

Shortage of Labor and the Hospitals.—A meeting of the Hospital Conference of the City of New York will be held at the New York Hospital, 8 West Sixteenth Street, on Monday, June 17, for the purpose of discussing the labor crisis and for the consideration of the advisability of appealing to the Federal authorities to institute measures of relief. The labor shortage, according to report, is now so serious that many hospitals are being obliged to curtail their work, and some are looking forward to the possibility of being compelled to suspend work entirely.

Presbyterian Hospital Would Cancel Agreement with Columbia University.—The Board of Managers of the Presbyterian Hospital have asked the trustees of Columbia University to join with them in cancelling the agreement which was made in April, 1911, having as its aim the establishment of a great medical center which should combine the College of Physicians and Surgeons of Columbia University with the Presbyterian Hospital in a new institution to be erected on Gun Hill Road in the Bronx. This request has been referred to the Committees on Education and Finance of the Board of Trustees of Columbia University for consideration. It is said that the plan of co-operation between the hospital and the university has worked admirably. The difficulties that have arisen relate solely to matters that have reference to plans for future development. It has so happened that while the hospital has funds with which to proceed with the plans laid out the University has no such funds and repeated efforts to obtain the necessary amount have been unsuccessful. It is also stated that the total cost of carrying out the plans of amalgamation has been found to be considerably higher than the original estimate.

Women Doctors Want Control of Medical College.—A committee of women physicians and surgeons who are members of the medical board of the New York Medical College and Hospital for Women have requested the Board of Regents to revoke the charter of that institution and to issue a new charter which will place the control of the organization permanently in the hands of women workers. This request is based on the charge that

certain men physicians as trustees of the New York Medical College and Hospital for Women have so far exceeded the authority vested in them under the charter of the institution as to render the charter inoperative, the claim being that the provision that the institution's functions shall be educational was contravened by a resolution adopted by the Board of Trustees abolishing the college and clinic of the institution and dismissing its teaching faculty. The trustees contend that their reason for abolishing the collegiate side and continuing the institution as a hospital was because the college was being conducted at a loss.

Plan Fight on Hookworm.—At the request of the Government the Rockefeller Institute intends to send an expedition to Jamaica to institute work looking to the eradication of hookworm. Dr. Howard, in charge of the work of the Rockefeller Commission to the West Indies, is expected here in the near future to discuss plans for the work which will be undertaken in cooperation with the Government.

Gets Wheat by Doctor's Prescription.—Twelve pounds of wheat flour was recently issued by the food administration of Dallas, Texas, on the prescription of a physician, who requested the flour for a patient suffering from pernicious anemia. For the past two months Texas has voluntarily foregone the use of wheat flour.

Dr. Charles Gilmore Kerley has resigned as Professor of Pediatrics at the New York Medical School and Hospital. His resignation took effect on June 1.

Dr. Livingston Ferrand, president of the University of Colorado, and **Dr. George E. Vincent**, president of the Rockefeller Foundation, have returned from France, where they have been engaged in antituberculosis work.

Medical Society Elections.—The FRANKLIN DISTRICT MEDICAL SOCIETY, at its annual meeting at Greenfield, Mass., on May 15, elected the following officers: *President*, Dr. Charles Moline of Sunderland; *Vice-President*, Dr. A. Mather of Colrain; *Secretary and Treasurer*, Dr. F. A. Millett of Greenfield.

THE WEST TENNESSEE MEDICAL AND SURGICAL ASSOCIATION, at its meeting in Nashville, on May 25, elected the following officers: *President*, Dr. John Yarbrough of Covington; *Vice-Presidents*, Dr. John D. Brewer of Newbern and Dr. Herman Hawkins of Jackson; *Secretary-Treasurer*, for life, Dr. George McSwain of Paris.

THE MANCHESTER (N. H.) MEDICAL SOCIETY, at its annual meeting, on May 24, elected the following officers: *President*, Dr. George S. Foster; *Vice-President*, Dr. Clarence O. Colburn; *Secretary*, Dr. John E. Holmes.

THE CONNECTICUT HOMEOPATHIC MEDICAL SOCIETY, at its sixty-eighth annual meeting, held in Norwich, elected the following officers: *President* (re-elected), Dr. M. D. Westervelt of New Haven; *Vice-President*, Dr. Willis S. Putney of Milford; *Secretary*, Dr. Herbert A. Roberts of Derby; *Treasurer*, Dr. Henry P. Sage of New Haven.

THE NEBRASKA STATE MEDICAL ASSOCIATION, at

its fiftieth annual convention in Omaha, on May 9, elected the following officers: *President*, Colonel John M. Bannister of Omaha; *Vice-Presidents*, Dr. Fred W. Buckley of Beatrice, and Dr. A. I. McKinnon of Lincoln; *Secretary-Treasurer*, Dr. Joseph M. Aitkin of Omaha; *Librarian*, Dr. William P. Wherry of Omaha.

THE WORCESTER MEDICAL SOCIETY, of Massachusetts, which met in Worcester on May 9, elected the following officers: *President*, Dr. W. L. Johnson of Uxbridge; *Vice-President*, Dr. William J. Delehanty of Worcester; *Secretary*, Dr. George A. Dix of Worcester; *Treasurer*, Dr. George C. Ward of Worcester.

THE KENTUCKY STATE HOMEOPATHIC SOCIETY, at its thirty-third annual meeting, in Louisville, elected the following officers: *President*, Dr. F. L. Juett of Lexington; *Vice-President*, Dr. Mary E. Hopkins of Louisville; *Secretary*, Dr. Joseph Winn of Louisville; *Treasurer*, Dr. Paul Kerkow of Covington.

THE NEW HAMPSHIRE STATE MEDICAL SOCIETY, at its meeting at Concord, on May 16, elected the following officers: *President*, Dr. Charles P. Bancroft of Concord; *Vice-President*, Dr. A. W. Shea of Nashua; *Secretary-Treasurer*, Dr. D. E. Sullivan of Concord; *Trustee*, Dr. Herbert L. Smith of Nashua.

THE TEXAS STATE MEDICAL ASSOCIATION, at its meeting in Dallas, on May 17, elected the following officers: *President-elect* for 1919, Dr. W. R. Knox of Houston; *Vice-Presidents*, Dr. H. Leslie Moore of Dallas, Dr. H. F. Connally of Waco, and Dr. L. J. Mankoff of Aransas Pass.

THE OKLAHOMA STATE MEDICAL ASSOCIATION, at its meeting in Tulsa, on May 17, elected the following officers: *President*, Dr. L. J. Moorman; *First Vice-President*, Dr. E. D. James of Miami; *Second Vice-President*, Dr. H. M. Williams of Wellston; *Third Vice-President*, Dr. Walter Hardy of Ardmore.

THE INDIANA ECLECTIC MEDICAL ASSOCIATION, at its annual meeting in Indianapolis, on May 16, elected the following officers: *President*, Dr. McG. Porter of Elkhart; *Vice-Presidents*, Dr. A. J. Ashabrammer of New Albany and Dr. J. W. Gage of Indianapolis; *Secretary*, Dr. J. E. Holmes of Indianapolis; *Treasurer*, Dr. C. A. Tyndall of Shelbyville.

THE CONNECTICUT STATE MEDICAL SOCIETY, at its annual meeting in Hartford, on May 16, elected the following officers: *President*, Dr. Charles J. Bartlett of New Haven; *Vice-Presidents*, Dr. F. E. Guild of Windham and Dr. J. H. Kingman of Middletown; *Secretary*, Dr. John E. Lane of New Haven; *Treasurer*, Dr. Phineas H. Ingalls of Hartford.

Obituary Notes.—Dr. J. HERVEY BUCHANAN died at his home in North Plainfield, N. J., on June 7, aged 47 years. He was a graduate of Jefferson Medical College, in 1896, a member of the American Medical Association, and the medical staff of the Muhlenberg Hospital of Plainfield.

Dr. JAROSLAV RADDA, a graduate of the University of Maryland, Medical College, in 1908, and of the Fordham Medical College in 1909, died at his home in New York City on May 5, aged 46 years. Dr. Radda was a member of the American Urological Society.

Correspondence.

QUININE AND WARBURG'S TINCTURE IN MALARIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In answer to the letter of Dr. H. Rabinowitsch, published in the MEDICAL RECORD of June 8, 1918, I would say: Of course, I am familiar with the fact that Warburg's tincture contains a proportion of quinine. Nor do I doubt that some of its remedial effects are due to the presence of this alkaloid. On the other hand, I also know and affirm again that in not a few instances quinine in similar or much larger quantity is wholly inadequate to effect a cure of malaria. Warburg's tincture in these instances effects the cure. Why, I cannot precisely say, nor can anyone else. It contains numerous drugs, and among them there may be some that are inert. It still remains true that the multiple combination does what nothing else known up to the present time effects in some most obstinate and imminently threatening cases. That, we know, as shown by repeated proofs and the published records of some of the best clinicians of former days.

"Ars longa, vita brevis." The greatest rôle of the physician is to cure and to relieve symptoms. Science, so-called and merely temporary, must give way to experience, based upon long and careful bedside observation of the wise practitioner. Only a few days ago the distinguished Surgeon General of our Army insisted in an address before the University and Bellevue Hospital Medical College upon the great value of the all-around doctor with our army at the front as compared with the specialist whose importance has a relatively limited field of work, in time of greatest stress. I wish particularly, at the present time, to insist that useful knowledge of our great forebears in medicine shall not be practically ignored. For this reason I wrote a strong word for Warburg's tincture in the treatment of malaria. In more than one of our latest and best works on the practice of medicine it is scarcely referred to.

BEVERLEY ROBINSON, M.D.

42 WEST 37TH STREET.

THE WAR AND INTERNES IN SPECIAL HOSPITALS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The inclosed is the result of inquiries made to the War Service Committee of the American Hospital Association. Believing that the information will be of interest to many, of value to some, and an aid to the Surgeon General's Department in carrying out its work, we are asking the prominent publications concerned in medical and hospital matters to assist in giving it publicity. Your cooperation will be very much appreciated.

R. P. BORDEN, Sec'y.,
Special Committee on War Service
American Hospital Association.

For two reasons the Department of the Surgeon General of the Army has signified its desire to promote the education of internes in proper hospitals for as long a period as the exigencies of war will permit: Primarily, that the future military surgeon may begin his

medical career with as much professional experience as possible; secondarily, so that the organization of hospitals for civilian treatment and for instruction of physicians and nurses may not be unnecessarily disrupted.

How far do these considerations apply to certain special hospitals such as hospitals for women, children, consumptives, eye and ear cases, and insane, and what should be the policy of the army with regard to internes in such institutions?

It seems clear that thorough education in all types of cases treated in the above, except maternity and children's hospitals, will have definite value for military purposes and that the same policy with regard to internes in these should be followed as in general hospitals. Probably the children's hospitals may be placed in the same category as the others, as the medical and surgical experience gained therein is such as to afford a substantial foundation for military service, and this taken into consideration with the desire to preserve the hospital organization should warrant the placing of children's hospitals on the same basis as general hospitals so far as interne service is concerned.

With hospitals for women the situation is very different. Service therein is intensive in a branch of medical science which has no direct relation to military needs and therefore such hospitals can not receive the same consideration as other hospitals as places of preparation for military service. On the other hand, it would seem that in such hospitals the organizations could be properly maintained by the aid of personnel not fitted for army service. Not every medical student is eligible for active military service of the kind to be anticipated and desired by the young medical man who has at last reached the place in his career where he can be of great value to the country.

General hospitals should give first choice to those who are physically fit for the work in the army and navy while young men who are not physically handicapped should equally seek internships in hospitals where they can obtain the best possible training for military service. Those who, by reason of physical disqualifications, are not entitled to enter the country's service in its military branches should welcome the opportunity to aid in its general efficiency by engaging in other work essential to welfare.

Thus, by co-operation between hospitals and between hospitals and student, can we come nearer a solution of the tremendous problem of making the supply of medical men meet the requirements of war.

With the use of women physicians, medical students and the proper allotment of student internes to places where they can be of the greatest use according to their qualifications, it would seem that an obvious difficulty may be at least minimized and the authorities in medical schools can aid materially in advising their young men as to the proper course to pursue. Some men who have a special interest in obstetrics and gynecology may dislike to abandon the opportunity to specialize in such branches during the period of their internship, and surely the country cannot afford to be without the services of men so especially educated, but the needs of our fighting men are immediate and imperative and our young men will no doubt be willing to sacrifice their personal ambitions for a time as many of the older men of the profession have already done.

The foregoing is the result of interviews with officers of the Surgeon General's Department by a representative of the American Hospital Association. It has been submitted to them and is believed to fairly represent the policy of the Department with regard to internes in special hospitals.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE LONDON WATER SUPPLY DURING THE WAR—AN EPIDEMIC CALLED BOTULISM—MEDICAL MEN AND THE NEW MILITARY SERVICE ACT—DEVELOPMENT IN THE ARMY MEDICAL SERVICE.

LONDON, May 16, 1918.

THE twelfth annual report of the Metropolitan Water Board made its appearance in the middle

of May, a date which implies remarkable promptitude inasmuch as the report gives the results of the chemical and bacteriological examination of all the sources of this London water supply for the twelve months ended March 31. Six weeks is not a long time in which to collate, print, and publish an elaborate document dealing with so many elaborate calculations. Dr. A. C. Houston, the director of Water Examinations for the Board, states definitely that, despite the disadvantages of a constantly changing staff, the work of water examinations has not been allowed to suffer appreciable diminution either in quality or quantity. Such a statement could not possibly be made in a public document, if all the proofs were not contained at any rate for those who can follow them in the document, and it is a remarkable testimony to the efforts of the staff. It suggests also that those who in the fourth year of the war are found acting as temporary substitutes in the delicate work of modern water examination, have proved themselves able recruits. There has never been a time when satisfactory evidence as to the purity and safety of the London water supply was more important, and the work of Dr. Houston and his staff deserves the greatest credit. Among the most interesting sections in the report are those which deal with the value of chlorine as a germicidal agent, and with the technical difficulties to be overcome, when adding the germicide to a water supply in the proper dose. Dr. Houston considers, as the result of practical experience during the colder periods of the year, that the gas must be added as a solution to the water to be sterilized unless some improved form of porous diffuser be discovered. From April 1, 1917, to March 31, 1918, 23,426,000,000 gallons of raw Thames water were chlorinated during 315 days (West Middlesex Supply Area) and 313 days (Staines Supply Area) out of a total of 365 days, the intermissions being caused by floods when the water was too turbid for filtration purposes and when the consumers had to be supplied with stored water. The percentage proportion of raw to stored water was 85 to 15, that is to say, that over 74 million gallons of raw water was daily treated with chlorine. No complaints whatever with regard to the chlorinated water were received as to the taste, while the bacteriological results were every whit as good as those obtained by storage, and what those mean in respect of *B. coli* we all know now. It has been demonstrated thus far that success in the chlorination of water supplies can be much more readily obtained when the air and water temperature are above a certain point.

The Medical Department of the Local Government Board obtained evidence by the second week in May of the presence in the community of an obscure disease manifesting a certain group of cerebral symptoms and attended with a case mortality of perhaps 20 per cent. None of the outbreaks was large, but their geographical range was an ominously wide one. This is the disease which was tentatively labeled "Botulism" by some of the medical observers who first called attention to its presence among the community in communications to *The Lancet* in the last weeks of April.

The term "botulism," of course, implies direct connection between the disease and food poisoning and should be confined to intoxication by the products of the *Bacillus botulinus*, described by von Ermengen, while later accounts of various outbreaks do not support the supposition that food, tinned or otherwise, plays a part in the infection. The official communication on the subject which has been issued by the Local Government Board to all medical officers of health of urban and rural sanitary districts alike describes the disease with perfect vagueness as an "obscure disease with cerebral symptoms," while in the medical press the disease has at various times been termed "infective ophthalmoplegia," "toxic ophthalmoplegia with acute asthenia," "toxic bulbar paralysis," "toxic encephalitis," "epidemic stupor in children," "X disease," "central nervous system toxemia," and Heine-Medin disease.

Dr. F. G. Crookshank, the medical registrar to the London Hospital, who is attached also to a general hospital at Hempstead, where cases came under his care, says that authentic accounts of outbreaks of botulism furnish no grounds for saying clinically that the cases differ in any way from certain types of Heine-Medin disease. As more and more cases occur at different centers, and the reports arrive with varying stress laid upon the different symptoms, the clinical identity of the epidemic with Heine-Medin disease appears to many observers probable. Many cases under observation were typical of meningomyelo encephalitis and none of the cases have been without many features which are characteristic of Heine-Medin epidemics.

In the meantime what label is to be affixed to a disease which has come in for much discussion, and will yet come in for much more? The convenience of a definite name for purposes of index and reference is obvious, just as the inconvenience is obvious of giving a name to a disease which implies for the conditions a wrong origin or a wrong pathology. There seems immediate room here for the medical etymologist. In the meantime the Local Government Board on May 15 have issued a schedule of inquiry to all medical officers of health following on the official summary of symptoms and asking for the sex, age, occupation, and environment of all cases; and observations with regard to symptoms, especially as pointing to various forms of meningitis, syphilis, diphtheria, or food poisoning. The medical officers of health are asked also to look carefully into the general food history of all patients, as well as the sicknesses which have really occurred among those with whom the patients have been in contact. In this way some material has already been obtained for a scientific investigation of the outbreak, which has now been undertaken for the Local Government Board by the Medical Research Committee.

The Director General of National Service has ahead of him considerable difficulty with regard to the calling up of medical men under the new Military Service Act. The extended age up to which medical men can obtain commissions makes it certain that a large proportion of those re-

cruited can only be intended for home service. There are three points which the Director of National Service has before him. The first two, in their order of importance, are: (1) Always to meet the needs of the Army at the earliest possible opportunity; and (2) to see that while attending to (1) no particular locality is unfairly denuded of medical men. The two prime points having been attended to, it is essential that the Director General should (3) judge fairly between medical man and medical man with regard to employment in his own area or employment elsewhere.

Probably all the medical men in the different areas whose age brings them within the scope of the new Act will undergo medical examination as a preliminary proceeding. This form having been complied with—and it is to be hoped that the examination will be a practical one and not merely a form—the Central Medical War Committee, the recognized recruiting body for the Army Medical Service, will consider which doctors can best be spared from which areas. This having been decided, the question will arise as to whether an individual doctor should be spared for military service direct, or to take the place of others who could accept commissions, or to obtain employment through the Ministry of National Service of a civilian kind. It seems at last as though the man power in the medical profession was going to be used with sagacity and economy. Developments in the Army Medical Service are following the same fortunate trend.

Surgeon-General Goodwin, the new Director General of the Army Medical Service, has lost no time in displaying the talents of energy, tact, and orderliness which his work, both with the British forces in France and with the mission to America, had led all to expect from him. Having reconstituted, and with a very strong personnel, a Medical Advisory Board for his Service, he immediately, as President of the Board, mapped out a program by which each medical section and surgical section of disease and injury, in the various stages from inception to convalescence, could be supervised by the highest available scientific authority.

The Board is already meeting regularly, Sir Bertrand Dawson, Sir Berkeley Moynihan, Sir Harold Stiles, Sir Robert Jones, and Surgeon-general W. H. Horrocks lending regular assistance, practical and advisory, both as to what should be done in their various departments and as to who is the right man to do it. To meet this latter and difficult problem, a rigorous card-index has been set up at Adastral House, the headquarters of the Army Medical Staff. By this index a complete register of all the officers, regular, territorial, and temporary, of the R. A. M. C. is being obtained, the entries showing the past work of every man, the posts that he has held, his proofs of special ability, and his record either in literature or research. With this index before them the Medical Advisory Board will be able to select for any post the man most calculated to fit it adequately, and the result of such discrimination cannot fail to be most valuable to the country, both now and in the future.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

INVESTIGATION OF TRENCH FEVER—HOW THE HUNS SHELL OUR STRETCHER BEARERS—RED CROSS STANDS BY BELGIUM.

Paris, May 1, 1918

A SCIENTIFIC investigation of trench fever, the disease which is causing an alarming wastage of man-power among the armies fighting in France, is now under way at the hands of the American Red Cross. The investigation has been entrusted to a staff of medical officers of the American Expeditionary Force, which, through the courtesy of officials of the British Army, is conducting its experiment at a British base hospital. Sixty enlisted men of the United States sanitary corps have unselfishly volunteered as living subjects for experimentation.

As the American Red Cross is seeking conclusive answer to the debated question of the transmission of the disease by lice, these sixty volunteers, all from New England, are serving in specified detachments, either as "hosts" to normal or infected lice, or have received injections of blood taken from soldiers known to be suffering from trench fever. They are quartered in four tents in the British hospital enclosure, back of the lines in the northern part of France. The Red Cross has provided comfortable walled hospital tents for the accommodation of the volunteers, laboratory assistants, and clerks and has transported to the hospital a complete laboratory equipment which will permit the most accurate study of the disease in relation to its transmission through parasites.

Trench fever is a new disease; it was unknown to the medical profession before the present war, and there is still little information of value in regard to it. But among the British troops at the front it is at the head of all the fevers and stands second in the list of those which cause the greatest wastage. It has caused almost one-third of all the sickness in some of the armies in the field in Northern France; in one division alone during a year the number of cases sent to field hospitals averaged 350 a month.

In employing the services of living subjects, this American Red Cross investigation is similar to that which was conducted many years ago in Cuba in reference to yellow fever. Trench fever, although absencing a soldier from his command for from six to eight weeks, is not fatal in its effects and leaves no permanent disabilities. It is the extended absence of the sufferer that has made the disease so alarmingly destructive of man-power at the front. It was with the approval of General Pershing that a call for volunteers to act as human subjects was made last month. There was no lack of volunteers. In transmitting the names of the sixty chosen for experimentation, the divisional chief surgeon wrote to the chief surgeon of the American Expeditionary Forces: "It is a subject of some pride in this division that practically all of the men of the 101st, 102nd, and 104th Field Hospitals, and the 101st, 102nd, 103rd, and 104th Ambulance Companies volunteered for this service."

The urgent need of determining the origin of the

devastating fever is announced in a memorandum sent to General Pershing last December by the chief surgeon of the American Expeditionary Force. After directing the commander-in-chief's attention to the sufferings of the British Army through trench fever in the last three years, he wrote: "On account of the scarcity of physicians in the British Army and the enormous demand made on them for duty outside the laboratories, the Royal Army Medical Corps has not yet been able to discover the cause of this disease, nor has it been able to prove the mode of transmission. The American Red Cross has set aside a sum for research work for determining the cause of those diseases, which are producing the greatest wastage in our armies. As trench fever is one of the greatest sources of wastage this subject is to be taken up first."

Trench fever became recognized as a distinct, specific infection during the latter part of 1915 and in 1916. While the first cases disabled the patients for only a brief period, the time a soldier is kept away from his command has materially increased in the development of the disease owing to the many relapses which occur in the majority of cases. The fever appears generally in one of two types, either as a short, evanescent fever, lasting for a few days or a week and frequently followed after a few days by a single short relapse or as an affection in which there is a series of relapses. The onset of the fever is sudden, as a rule, and marked by headache, dizziness, pains in the back, and particularly in the legs, and a sharp rise in temperature. Pains in the shins is a common complaint by patients and is often very distressing. The pulse is usually in the neighborhood of 100, and the heart is normal in the early stages of the disease. Disordered action of the heart is very common after the severe cases. Medical experts of the British Army have demonstrated that it is infectious through transmission of it to healthy men by injection of blood taken from patients during the acute stage of the affection. As the incubation period of the disease has been known to extend to twenty-two days, it is not possible at present to announce more than the inauguration of this important work, but it is hoped that the result of this American Red Cross investigation, aided by the devoted service of the volunteers no less than by the skill of the medical experts of the American Army, will be the solution of one of the greatest problems of the war. The writer published a paper in the *MEDICAL RECORD*, July 28, 1917, describing this fever.

How American soldiers, new in the war game, beat down a determined attack made by veteran Germans; how American lives were risked to bring in a wounded German prisoner, and how the Y. M. C. A. is seeking to do its bit "up front" as elsewhere, was told recently in an address by Mr. D. A. Poling, who is in France for the World's Christian Endeavor Union. Mr. Poling was at the front when fighting took place, working in one of the advanced Red Triangle centers which give hot drinks to soldiers and offer other comforts to the men, and from which workers go out into the trenches to be of such service as they may.

"The French were ready to back up the Americans in this big raid," said Mr. Poling, "but the

'poilus' who were in behind our lines were not called into action, as never a German got through. Our men withstood a terrific barrage and then smashed the German infantry attack before it got past the first trenches. An accident during the heavy fighting in the afternoon shows the chivalric stuff American men are made of. The secretary, in whose hut I was working, and I, were helping some stretcher bearers to bring in a wounded German. We could not get through the trenches at this point, so started across an open space toward battalion headquarters, a little way back. Then hell broke loose. The enemy saw the party of stretcher-bearers and opened a fierce fire. We fell to the ground and waited a bit. Scared? Well, I never before knew what it was to be genuinely scared. Finally, when the fire did not cease we ran for it and got through, all of us, without injury, though one of the soldiers was blown about 5 feet by an exploding shell. The incident was reported to the major. He asked where the prisoner was, and being told the facts, said 'He is a Hun, but we are Americans; bring him in.' Two lieutenants took charge of the men that went back and my companion of the Y. M. C. A. went along to show them where the prisoner was left. Soon the enemy guns broke loose afresh and I knew this party had been sighted and was being shelled. It seemed a long time waiting back there to learn what was the fate of those soldiers and of the secretary. Finally I went down the road a bit and there met them coming in, all well. You see the officer in charge of that party knew the contour of the land and immediately after picking up the stretcher with the prisoner on it they skirted under a rise of the ground and thus evaded the shells. After a strenuous day we came back to our hut. The secretary asked the sentry to inform men returning from the trenches that the Y. M. C. A. would be open. These men were due to come in about 3 A. M., and when they came they found hot drinks awaiting them. It was as little as any one could do, opening up at 3 A. M., when one stops to think that a soldier endures day in and day out hundreds of experiences similar to the one which is easily the most thrilling of my life."

The Belgian front has just received a visit of a deputation of the United States Red Cross, comprising Mr. Eliot Wadsworth, vice-chairman and member of the Council of War of the Red Cross; Colonel Ernest P. Bicknell, Majors John Van Schaick, Ivy Lee, and Simmons. The deputation went about the Belgian trenches, military hospitals, and civil schools established almost immediately behind the fighting lines. On leaving, Mr. Wadsworth stated to General de Ceuninck, the Belgian War Secretary, that he and his colleagues were on the point of returning to the United States to organize a fresh fund for the American and the Allies' war and benevolent institutions, and he added: "Our visit to the Belgian front has been for us a most precious lesson. It has afforded us the opportunity of admiring the pluck and undying confidence of the Belgians, from the general in command and the soldiers under his orders, down to the young children quietly studying in school, amid the hell of German artillery

firing close by. The cheerful determination of the soldiers and the population to go on fighting to the end, to the day of victory, must most powerfully strike any American visitor. As one of the directors of the United States Red Cross I here express the resolution of the 22,000,000 members of our organization to assist Belgium and its marvelous work, not only for the relief of all who are suffering from the war, but in order also to assist in winning this war. America will be at your side until the victorious end!"

116, AVENUE DES CHAMPS ELYSÉES.

MEDICAL WEEK IN CANADA.

(From Our Special Correspondent.)

HAMILTON, ONTARIO, June 1, 1918.

THE eighteenth annual meeting of the Canadian Association for the Prevention of Tuberculosis was held in Hamilton on Wednesday, May 29. Addresses of welcome by the Mayor of Hamilton, Chas. G. Booker; the president of the Ontario Medical Association, Dr. J. P. Morton, and others. Social and Public Health Aspects of Tuberculosis; "The Secretary's Report," by Dr. Geo. D. Porter, Toronto; "Rôle of Health Officers in the Control of Tuberculosis," by Dr. Geo. D. Porter, secretary of the executive council, in his annual report, gave an exhaustive account of the year's work. After stating that satisfactory progress had been made, he gave as an instance the great increase in the accommodations for the tuberculous owing to the problem of the returned soldier. It was pointed out that despite the war, education by publicity had been carried on widely, thanks to the Federal grant. Allusion was made to the opening of the new sanatorium in London and to the new hospital in Quebec which would accommodate 100 patients. The statement was made that records of those rejected on account of tuberculosis could be obtained from the army, and these cases followed up in an educational way, as done in the United States. It was urged that food production should be increased as a means of keeping up the vitality of the people and thus lessening the menace of tuberculosis.

Capt. H. W. Hill of London, Ont., said that tuberculosis should be dealt with on similar lines as any other infectious diseases, by discovering the sources and stopping further spread from them. In short, by blocking the routes of spread from unidentified sources, so far as our present knowledge admitted of such a procedure. Education of the public was also a factor of great importance in the prevention of tuberculosis. The public should be so enlightened that every one, as a matter of course, would avoid all sources and block all routes of infection of whatever nature, and would aid in the search for any system of protective operations which might enable the human body to resist the disease. Routine methods were outlined briefly by Hill. Diagnosis as to whether the case is an open or closed one. Isolation, if necessary, and if not necessary, advising as to treatment and keeping the case under supervision. Open cases in children were fortunately very rare. It was pointed out that it was essential to differentiate between the human and bovine forms of disease. Pasteurization of milk would end bovine tuberculosis. Hill laid especial emphasis on the fact that open cases should not be allowed to com-

mingle with closed cases, and in his opinion open cases should not be allowed to mix even with open. He was not a believer in the widely held view that tuberculosis is almost always contracted in childhood. He thought that a very large number of cases were contracted after the age of sixteen. Hill advised sanatorium treatment for open cases occurring in childhood. Open cases found in a family should lead to an examination of the other members of the family and of their close associates. It may be said that the local courts in London, Ont., and vicinity, over which Captain Hill is health officer, have strongly supported his compulsory methods of dealing with tuberculosis. Captain Hill asked why syphilis could not be dealt with in the same way.

The president of the association, Dr. I. A. Machado, delivered an address in which he advocated the federation of all the agencies cooperating in the work. The speaker gave high praise to the work being done by the invalided soldiers' commission in Canada, which he said had opened the eyes of thinking soldiers to the splendid accomplishments possible in the treatment of tuberculosis.

Dr. John H. Prior of Buffalo gave a concise description of the Rollier treatment. He said that it involved a great deal more than heliotherapy, and included special appliances and methods of extension and fixation devised by Rollier. The treatment was a great addition to measures usually in vogue with the view of benefiting various forms of tuberculosis. He emphasized the point that the improvement of general condition and increase of resistance was a prime necessity of treatment if successful results were to be looked for, and argued that the Rollier treatment was of very considerable assistance in gaining this end. A description of the routine employed at the J. N. Adam Hospital, Buffalo, was given, and some of the difficulties met with in the application of the method were entered into. The results obtained in bone, peritoneal, and gland cases were considered at some length.

Dr. J. S. Pritchard of Battle Creek discussed the differential diagnosis of tuberculosis. He pointed out that the danger of errors in diagnosis was often made by arriving at a too hasty conclusion on limited evidence, such as indefinite physical findings. Attention was drawn to the fact that moisture might persist in the chest for months in non-tuberculous pathology, and that localized râles were not always caused by a tuberculous lesion; that clinical symptoms must be carefully investigated; and finally, that it was necessary to acquire an adequate knowledge of internal medicine in order to become proficient in any specialty.

Artificial pneumothorax was the subject of a paper by Dr. C. D. Parfitt. He gave an analysis of the results obtained by artificial pneumothorax during a period of five years. A series of efficient compressions was contrasted with another series of cases in which the procedure proved to be impossible, in order to show the relative value of the method. The several incidents and complications which had been met with were described, and a series of case records was given. Indications for the employment of artificial pneumothorax were given at considerable length.

Dr. A. F. Miller of Kentville, N. S., discussing sanatorium treatment and results, gave a brief history

of the evolution and development of the sanatorium. While admitting that rest and exercise, employed judiciously, were important factors in sanatorium treatment of pulmonary tuberculosis, he said they were by no means the sole methods by which the course of the disease could be arrested or improvement promoted. The treatment of tuberculosis did not begin and end with fresh air and exercise, nor fresh air and rest, but according to Dr. Miller the three, properly proportioned, brought results. While it was granted that sanatoriums had not come up to the expectations of the public, it was claimed that the public was more or less ignorant of their functions. Standing by themselves they could not reduce to any appreciable extent the spread of the disease. In his opinion the State should provide local clinics for those who took home treatment. With good after care in the homes of the patients those in charge of sanatoriums would try to carry out the work they were intended to carry out.

The last paper read at the meeting was on tuberculin treatment, by Dr. J. H. Elliott of Toronto. A résumé was given of cases, principally of the non-pulmonary type. It was shown that splendid results had been obtained in cases of glandular tuberculosis, tuberculides, and tuberculous sinuses following spontaneous evacuation of abscesses, or following operation for relief of various tuberculous conditions.

J. A. Machado of Ottawa was again elected president of the association, Dr. George D. Porter of Toronto secretary, and Sir George Burn of Ottawa treasurer. The vice-presidents were Lieut.-Col. McKelvey Bell, Mrs. P. D. Cerrar, Hamilton, and E. L. N. Clubbett, Hamilton.

The election of officers of the Canadian Medical Protective Association resulted as follows: Dr. R. W. Powell, Ottawa, president; Dr. J. A. Cannard, Sherbrooke, Que., vice-president; Dr. J. Fenton Arque, Ottawa, secretary-treasurer.

2. The Physician and Psychology.—J. Danforth Taylor impresses upon members of the profession the importance of the study of psychology, which has been well described by McDougall of Oxford as "the study of behavior." For the successful practice of medicine naturally the first requisite is a complete knowledge of medicine and surgery in its various branches. This alone is not sufficient, however; it must be supplemented by common sense in the application of that knowledge, a neat personal appearance, correct habits, a courteous manner, and, what is important, ability to "size up" the other fellow, as Taylor puts it. But beyond all this the successful physician requires a practical psychology—embodying *suggestion*, *sympathy* and *imitation*. For instance, the physician should *suggest* by his manner that he is interested in the patient and should show a *sympathetic* interest in him and his family. The hypnotic effect of a well modulated voice upon the patient's nerves must also be remembered. Assured that "there is hope" and that with care and proper attention to directions given there is every prospect of

cure, the patient leaves the doctor's office better in mind and body. The physician has given his message to a receptive mind and his success is assured in 80 per cent. of cases. The patient's primitive sensations have been appealed to and stimulated. His *visual* sensations have recorded the courteous manner and, if the physician dispenses his own drugs, have seen the medicine prepared; his *auditory* sensations have been pleased with a well modulated voice which has assured him of relief, and his *tactile* sensations have felt the package containing the remedy. He feels that the doctor is in sympathy with him and unconsciously he tries to *imitate* a man of stronger mentality and fall in with his suggestions. Association may also play a part here; previous success that the physician has had with the patient or with his friends impresses upon his mind more forcibly the thought that he will be well. Thus the physician is able to treat the mental as well as the physical condition of the patient. Taylor concludes: The study of psychology is a review of the behavior of all peoples at all times and in all conditions. It is a college education in itself. Why not look into it?

3. Infection of Children with the Tubercle Bacillus.—E. Mather Sill tested for the von Pirquet reaction 658 children up to thirteen years of age, who came to his clinic for various reasons during a continuous period of four months. The children came from families living in congested districts on the lower East Side of New York, in which there was no history of tuberculosis. A positive reaction was given in sixty-one cases, or 9.2 per cent. The author compares these findings with those of other observers. Lamson at the University of Minnesota in 1913 found that 2.5 per cent. of individuals in non-tuberculous families showed evidence of infection, 22 per cent. in families where there was latent tuberculosis, and 67 per cent. in families in which were open cases of the disease. Manning found that 22.8 per cent. out of sixty-two children in Seattle gave a positive reaction. Alan Brown found that 67.21 per cent. of babies exposed to tuberculosis were infected and of these 60 per cent. died of the disease. Fishberg found 67.25 per cent. of 692 children living with tuberculous parents in tenements in New York City gave a positive von Pirquet reaction. In private practice Cattermole of Colorado tested sixty-six children, ranging in age from one to fourteen years; 38 per cent. were positive. All showed symptoms which might be due to tuberculosis and thirty-four had tuberculous parents. In Cattermole's series twenty-two tuberculous and twelve non-tuberculous children had tuberculous parents, and one tuberculous child had non-tuberculous parents. Mather Sill points out that the younger the child is the greater is the danger of infection resulting in clinical tuberculosis and death. (In Brown's series 70 per cent. of infants under two years of age giving a positive reaction, and 60 per cent. of those with a family history of tuberculosis, died.) He also points out that when the reaction comes up quickly it indicates an active focus, whereas a delayed reaction indicates a latent process. A comparison of the figures of American observers with those of Hamburger and Monti shows the incidence to be much greater in Vienna, although it varies in different cities in the United States. In Mather Sill's series infection was rare up to the fourth year of age and when it did occur it usually meant tuberculous disease, invariably so in those under two years of age. From the fourth to the thirteenth year there was a steady increase of infection, and from the tenth to the twelfth the percentage of infections was nearly three times that from the eighth to the tenth year. From the twelfth to the

thirteenth there was a marked increase in infections over the preceding years, being more than three times that from the eighth to the tenth year. He found that older children appeared to be more resistant to tuberculous disease, but more liable to infection from sources outside the family. The cervical glands were frequently the chief seat of involvement, the tubercle bacillus no doubt entering by way of the tonsils and adenoids. He refers to the observations of Park and Krumweide, and Mitchell of Edinburgh, which have shown that in a large percentage of such cases the infecting agent is of the bovine type. He considers the von Pirquet cutaneous reaction one of the most reliable aids to diagnosis, and states that in infants under two years it usually means a recent infection and active tuberculous disease. A persistently negative reaction, except in very ill patients and those with measles, excludes tuberculous infection. The Roentgen ray this writer considers also of great assistance in the diagnosis of tuberculosis of the lungs or tracheobronchial glands. Not only can the extent and location of the lesion be ascertained by its use, but also the character of the lesion. He attaches the greatest importance to the examination of milk intended for the use of infants and young children, in view of the fact that so large a percentage of cases of infection are due to the bovine type of bacillus, and recommends that all milk should be heated to a temperature of 140° F. for twenty minutes before being given to infants, should any doubt exist as to its purity.

1. Use of Corn (Maize) as Human Food.—H. C. Sherman points out that if one-fifth of the total corn crop of this country were consumed for human food, it would set free all the wheat needed for our Allies and still leave enough corn on the farms for the adequate feeding of live stock. A series of experiments have been carried out in healthy men and women by the department of food chemistry at Columbia University in cooperation with the New York Association for Improving the Condition of the Poor, special attention being paid to digestibility and nutritive value of corn proteins. In the first experiment a diet consisting very largely of wheat bread was first taken, one third of which was later replaced by an equivalent amount of corn in the form of mush. In the second experiment a low protein diet was given, 200 gm. of cornmeal being used daily, 90 gm. in the form of mush and 110 gm. mixed with wheat flour and eaten as bread. The third subject consumed 110 gm. of cornmeal per day for eight days, after being twenty days on a diet consisting largely of bread made in part from patent and in part from whole wheat flour. In all three cases slight digestive disturbances resulted, which however might be attributed to the use of a bulky and starchy diet during the summer months, when these experiments were undertaken. A fourth experiment was therefore made and cornmeal in still larger quantities given in the form of thin scones, so that the starch was more uniformly heated and more thoroughly cooked. This diet was taken for a month without disturbance of appetite or digestion. Determination of the nitrogen balance showed that the maize protein functioned with unexpectedly high efficiency, since the equilibrium was maintained throughout the month and the body weight of the subject remained constant. It is evident, therefore, that cornmeal suitably cooked can be substituted for wheat products even to the extent of the whole usual consumption of wheat in the dietaries of those who live largely on bread. It is also evident that corn prod-

ucts, if suitably cooked, can be introduced into the dietary of those not accustomed to their use without any effect upon digestion. The author gives a week's menus, in which 50.5 per cent. of the calories are contributed by corn products. Such menus, however, should be supplemented by a liberal use of fresh fruits and vegetables. In regard to the continued use of cornmeal in the dietary, Sherman refers to the animal experiments carried out by McCollum, who has repeatedly stated that wheat and maize are very similar in their dietary properties. He also reminds us that Osborne and Mendel, to whom we owe in great measure our knowledge of the deficiency of zein, have shown that the other important protein of corn, maize glutelin, is adequate to meet all protein requirements and maintain a normal rate of growth when fed as the sole protein of the diet. These observers have also shown that zein supplemented by a much smaller amount of milk protein may take the major part in meeting the protein requirements either of maintenance or growth. Sherman adds that the exclusive and persistent use of any one grain leads to unfavorable results, but that the substitution of corn for half of the wheat usually consumed may improve the biologic value of the diet. Seeds, however, should be supplemented by leaves and tubers and by milk, which latter forms the greatest factor of safety in our diet. Referring to pellagra, he says the cause is not to be found in the use of cornmeal but rather in the lack of a sufficient quantity of other foods. He closes with a plea for the fuller use of corn as human food in view of the fact that the wheat situation is becoming constantly more acute.

1. Cerebral Edema (Excess Cerebrospinal Fluid): Its Causation and Surgical Treatment.—Major L. Bathe Rawling makes this contribution to the study of cerebral edema as a result of his Eastern experiences. He applies the original term "excess cerebrospinal fluid" to the naked eye appearance of brain and membranes when soaked in an excess of fluid, "cerebral edema." This writer first discusses the conditions met with in cerebral edema, and its cause. Disagreeing with Halliburton, he believes there is a very definite relation between the amount of cerebrospinal fluid present intracranially and the intracranial venous pressure, for the following reasons: (1) It is accepted that the cerebrospinal fluid is formed either as an active secretion from the choroid plexuses of the lateral, third, and fourth ventricles, or by a process of filtration through the choroid capillaries. (2) It is accepted that the greater part of this fluid passed from the ventricular spaces through the foramina in the roof of the fourth ventricle to the cerebral subarachnoid system and spaces. (3) It is accepted that it exists at very much the same pressure as the intracranial venous system, but slightly above the venous pressure. (4) It is accepted that, under normal conditions, it is absorbed, as formed, into the cerebral venous channels, more especially into the lateral lacunæ of the superior longitudinal sinus. It would be unwise, in the present state of our knowledge, to make any very definite statement as to whether this is a mere mechanical transmission of one fluid of a lower specific gravity and of higher pressure into another, through a permeable wall, or whether the walls of the veins possess a certain selective action. In all probability the vessels do exercise a selective action, but, under the more ordinary conditions, the absorptive process is probably purely mechan-

ical. Anyhow, this venous absorption must be dependent on the healthy condition of the walls of the cerebral venous channels, and on the intracranial venous pressure. Consequently, if for any reason the absorptive capacity of the veins is impaired, either by disease or injury, due absorption cannot take place and cerebrospinal fluid collects in excess in all possible spaces—in the subarachnoid system, in the ventricles, on the surface of the brain and in the subdural space, producing, as a result, a typical state of cerebral edema. For example, if, as the result of heat-stroke, the tunica intima of the cerebral sinuses and veins is impaired, temporarily or permanently, cerebrospinal fluid will collect in excess. Again, if as the result of some head injury the intracranial venous pressure is considerably raised, so as to be well above the tension of the cerebrospinal fluid, the normal rate of absorption of cerebrospinal fluid will be impeded, and it will collect in excess. As regards the hypothesis that toxic conditions, acting on the choroid plexuses, lead to an increase in the rate of secretion, the writer believes that there is no particular evidence of this. In his work in the East, Rawlings treated a number of patients suffering from "heat effects," the symptoms being headache, usually frontal, and worse between 5 and 8 P.M., and general mental effects; vomiting; ocular changes; slow pulse (50 to 60), and rise in systolic blood pressure to 140 or 150 mm. Hg. (it was found that the average blood pressure of patients in India was below the normal); exaggeration of superficial and deep reflexes; slight rise of temperature, more marked during severe headaches, and epileptiform convulsions, several of the cases giving a previous history of brain disturbance. Decompression was done in seven cases with satisfactory results, and in four cases which refused operation the fits and headache grew more severe and the patients were eventually discharged in a rather pitiable condition. Rawling points out that all the symptoms mentioned point to an increase of intracranial pressure and the satisfactory results obtained by decompression would seem to show that the excess of cerebrospinal fluid was directly responsible for their development. He states that as all the cases recovered he has not had an opportunity of putting his views to the test by obtaining microscopical evidence as to pathological changes in the cerebral veins. He adds that, of course, lumbar puncture can only bring about temporary improvement, and more radical measures are required for the relief of the accumulating fluid. He found also that in some cases lumbar puncture made the patients worse, and that in others failed to show any excess, but rather the reverse. In one of his cases four punctures carried out immediately previous to operation showed a great diminution in the amount of cerebrospinal fluid, whereas in the operation performed immediately afterward the opening of the dura showed a most typical condition of cerebral edema, with very great excess of fluid. He suggests that in such instances some swelling in the membranes in the region of the fourth ventricle, together with considerable local excess of fluid, closed the normal communication between the cerebral and spinal arachnoid system. He believes therefore that the general clinical symptoms are a surer guide.

A Method for the Examination of the Cerebrospinal Fluid with Colloidal Solutions, "Mastix."—E. Jacobsthal and V. Kafka have examined the cerebrospinal fluid of divers cases from the viewpoint of their reaction of precipitation in relation to colloidal solutions. The technique of their researches, which appears to the reviewer quite precise, but liable to serious errors if not carried out in the most minute detail, consists essentially in the production of a cloudiness and then precipitation in the mixture of the colloidal solution with progressive dilutions of spinal fluid. The dilution is made in a solution of NaCl, which has, in the first place, been accurately estimated from the standpoint of its precipitating properties. The writers have been able to qualify various types of spinal fluid, characterized by their differing charted curves of precipitation for progressively diminishing concentrations. A series

of charts are reproduced, beginning with the normal curve of the cerebrospinal fluid and going down the line to that of general paralysis. Simple syphilis, beginning tabes and cerebrospinal syphilis offer just so many transitory forms following each other. In a general way, this progression appears to consist in a progressively marked precipitation by the use of progressively concentrated solutions. The dilute solutions varied much less, as far as their precipitating properties are concerned.

Acoustic Examination from the Standpoint of Military Aptitude.—E. Wertheim reviews the various tests, all of which are rather familiar, in order to estimate the reality of deafness said to exist by the candidate. To these methods of examination the writer adds that of provoked nystagmus after Barany's method, which alone offers a positive result and speaks in favor of a perfect integrity of the internal ear. Besides this, Wertheim describes a procedure of his own. After the ordinary tests, at the time that the soldier under examination supposes that the examination has ended, a short ocular examination is made as if to estimate the mobility of the eyes. The attention of the subject being thus fixed, he is told to close the eyes, this being suddenly said in a low tone. A simulator who is no longer on his guard closes the eyes or starts to do so, but will interrupt it at once.

March 12, 1918.

Neurosexual Observations at the Front.—Lissmann publishes his notes made during a campaign of three years on the sexual life of a battalion composed of men varying in age from 30 to 45 years. He believes that masturbation was not practised by these men. A too abundant regimen and gastronomic dainties sent to the men during 1915 caused manifest pathological symptoms in their sexual life, such as irascibility, anguish, mental depression, etc., symptoms which disappeared after pollution took place. The prolonged effect of abstinence appeared to be a diminution of the sexual instinct. The writer did not meet with any instances of homosexuality resulting from the conditions imposed by war.

Gas Intoxication in X-Ray Rooms.—H. Wintz does not believe that the gases developed by the sparks are the principal factors of the disturbances met with in radiologists. He has measured the proportion of nitric acid and found the quantity so small that it need not be taken into consideration. Wintz thinks that ozone and its derivatives which are produced by the effect of electric discharges are the causative factors of headache, bodily fatigue, disturbances of the attention and memory. As to treatment, the writer advises the isolation of the tracts, followed by the sparks, the use of polished cables or tubes in place of high-tension cables and the more general use of aeration apparatus.

The Spontaneous Cure of Carcinoma, Particularly Cancer of the Stomach.—G. E. Konjetzny studies the processes of organic defense which may result in total or partial destruction of a neoplasm in evolution. He refers to cases of gastric cancer which may be mistaken for ulcers on account of the continued destruction of the epithelioma occurring as fast as the neoplastic production. Besides certain gastric cancers (fibrous carcinoma) are characterized by a diffuse neof ormation in the stomach layers and histological examination shows that some areas of the growth are undergoing destruction from the influence of the fibroblastic reaction of the tissues. Konjetzny has found in 60 per cent. of operated gastric cancer epiploic metastases, and in them he maintains that he was able to detect processes of victorious defense against the cancer cells. From these data he offers very optimistic conclusions as far as the mobility of certain metastatic cancers is concerned. The paper is one of the German scientific pipe-dream variety, long known to the medical profession.

March 19, 1918.

On the Technique of Operation for Goiter.—Wilms, basing his remarks on a total of 2100 cases, believes

on the increase. The two dangers are injuries to the recurrent nerve but they can be avoided if modern methods are closely followed. For this reason they should be removed. The writer usually follows the following technique: Freeing of the gland as ordinarily done; ligature of the vein of the capsule on one side; delivery of the gland by the aid of numerous hemostats applied to the capsule; ligature of the superior and inferior thyroid arteries. The inferior thyroid is ligated half way between the carotid and the gland, the recurrent nerve is not isolated, while the parathyroids are sufficiently far away from the point of ligature so that there is no danger of injuring them. In very vascular goiters one may ligate all four arteries without fear. Colloid goiters are poorly vascularized so that ligature of one artery on each side is quite sufficient. Sauerbruch's technique for retrosternal goiter, by splitting the sternum and retracting the incised edges, offers no particular advantage, as the ordinary technique of these goiters permits their delivery.

The Removal of Foreign Bodies from the Pleural Cavity.—H. G. Pleschner advises the use of the endoscope for the localization and removal of these foreign bodies under the control of the sight. These foreign bodies consist of bits of missiles, gauze sponges left in the cavity and pieces of drainage tube which have slipped in. The cystoscope is far less practical than a straight endoscope, the esophagoscope or rectoscope. Drainage tube in the pleural cavity is readily recognized with the endoscope, but one should never seize them at the portion which presents to the view; they are to be seized at one end; otherwise the tube will break and the resulting bits must each be removed. Pleschner concludes this extraordinary contribution (which is a confession of very careless surgery) by relating the case of removal of a biliary calculus from the choledochus through a cholecystotomy fistula by employing an endoscope for locating and seizing the stone.

Deutsche medizinische Wochenschrift.

March 18, 1918.

Theory of Selection (Selektionshypothese).—L. von Liebermann, in a purely theoretical article, maintains that it is proper to include all serologic reactions (immunity, alexis, anaphylaxis) in the general law of reaction resulting from the struggle between the tissues and bacteria. Thus, the weakened cells of the infected organism are destroyed and become antibodies, while their ultimate degeneration produces toxins which give rise to the phenomenon of anaphylaxis.

Experiences with Malaria and Its Treatment.—A. Schittenhelm and K. Schlecht refer to the importance of "plasmodium carriers," not only from the standpoint of the constant menace of an attack of the disease, but also from the viewpoint of their danger to others. The writers are of the opinion that dissemination of the disease, as well as its annual recrudescence, is above all the result of a periodical infection of mosquitoes, an infection derived from malarial patients as well as carriers of the organism. The writers insist, therefore, on the necessity of detecting and treating these "carriers." They can be detected by the injection of various substances, such as milk or salvarsan, or by the quartz lamp, over the splenic area. The writers employed adrenalin, which causes the organism to leave the spleen and enter the circulation as much from the contraction of the gland as from sudden change in pressure. Considering the question of acquired quinine tolerance after prolonged exhibition of the drug, the writers conclude that this does not occur, as these patients eliminate the quinine by the urine quite as slowly as those who begin a treatment for the first time. The writers advise intensifying the doses of the drug as follows: 1 gram, 20 centigrams for three days; 1 gram, 50 centigrams for three days; 1 gram, 80 centigrams for four days, these being the daily doses given fractionally in 30 centigram tablets. The treatment is continued by diminishing the daily dose. The combined salvarsan-quinine treatment is to be recommended in obstinate cases.

Wiener medizinische Wochenschrift.

March 23, 1918.

Pathogenesis of the Pemphigus Bullæ.—F. Samburger at length concludes this long article on the respiratory functions of the cutaneous surface of man, and ends with a study of the anatomical distribution of the cutaneous blood vessels from the viewpoint of this function.

Trachoma.—L. Königstein, in this article, concluded from the previous issue, takes up the treatment of this process and remarks that the ordinary methods advised are usually both long and fruitless. The writer has essayed injections of milk as advised by some, without obtaining any appreciable result. Subconjunctival injections of sublimate only produced temporary improvement. On the other hand, a popular remedy employed in Galicia, namely, the application of leeches to the tarsal conjunctiva, gave a few successful results which were really remarkable. As an operative procedure Königstein usually prefers excision of the conjunctiva. His general results have been satisfactory, inasmuch as 40 per cent. of the cases were able to return to military service and 30 per cent. were discharged without secretion; in other words a total of 70 per cent. The writer ends by an enumeration of certain general measures of a social kind, apt for extinguishing this ocular affection.

Partial Cephalic Nystagmus of Nurslings, Considered as a Vestibular Reaction of Rotation.—S. Gatscher has studied (just why it is impossible to say) the movements of the head in nursing infants following on a passive rotation around the longitudinal axis of the body. These reflex reactions are more evident in the infant who has not as yet learned to hold up his head, this being due to the lax condition of the muscles, whose contraction, in the adult, prevent reflex reaction of the head. The infant responds to rotation in one direction from a reflex of the head in an opposite direction to the rotation. At the time of the cessation the derivation suddenly changes the direction. Therefore, it is a phenomenon similar to the vestibular phase of ocular nystagmus; when the latter exists simultaneously with rotation of the head, both phenomena are of the same duration.

Wiener medizinische Wochenschrift.

April 6, 1918.

Partial Cephalic Nystagmus.—S. Gatscher draws the following conclusions from his case reports given in the preceding issue. Passive rotation around the longitudinal axis of the body produces, in the infant, an active derivation of the head in an opposite direction to that of the rotation. This reflex is a connexe phenomenon of the slow phase of vestibular nystagmus which takes place in the same direction.

The Vitamines and Their Relation to Metabolism.—R. Kleissel offers a long article devoted to theoretical considerations relative to the pathogenesis of scorbutic states. The chemical study and analysis of vegetables which favorably influence the disease have shown that their action is related to a precipitate which is obtained with phosphotungstic acid. By progressive fractional analysis it has been found that the curative effect is obtained from the moment that Millon's reaction is no longer present in the residues of the analysis. The writer recalls the part played by plants in the synthesis of the more complex bodies, as well as the association of certain substances with chemical combinations which appear to increase the activity of these substances. Such for example is the part played by acids which increase the stability and at the same time reinforce the action of vegetable matter (the action of lemon juice in scorbutus). To conclude, Kleissel insists on the part played by tyrosin, which is absolutely requisite for the synthesis of the albuminoids.

Annales de Dermatologie et de Syphiligraphie.

September, 1917.

General Conception of Dermatoses.—Brocq makes the following scale for the intensive study of skin diseases: 1. Elementary lesions. (This, of course, is the time-

honored first study objective.) 2. The objective syndrome. This aspect of dermatology has not heretofore received much cultivation. The prurigenous rash is a conspicuous example. The author would make elephantiasis a syndrome because it originates in any affection in which the veins and lymphatics are obliterated. He would also term pemphigus a syndrome, for it, too, accompanies numerous affections. Cutaneous gangrene also belongs here. Syndromes of this class have to be differentiated from actual diseases—idiopathic affections. There is another group, however, the members of which stand forth clearly as syndromes which are not confused with diseases. These are always due to lesion of some other organs of the body. In hypothyroidism, in renal impermeability, in autointoxications, we may see cutaneous syndromes. The phenomenon is due largely to individual peculiarity or disposition. The author goes much further, however, for he temporarily regards as a syndrome any affection which has no definite proved causation; and from this viewpoint even eczema and psoriasis are only syndromes which occur under the greatest variety of circumstances. Let us suppose that renal impermeability causes a pruritus which as a result of scratching and rubbing becomes an eczema. The syndrome, however, may be understood better if we first consider the true diseases. Here belong naturally all the affections due to fungi, bacteria, and animal parasites, and these considered broadly are very numerous, especially in the tropics. Here belong the whole of cutaneous syphilis, leprosy, tuberculosis, frambesia, blastomycoses, etc., the pyodermites, the tineas, scabies, pediculosis, etc. Here might also be placed the occupation dermatoses and results of local irritants in general. It is evident that such a grouping is not a stable one, but it is thoroughly practical, for it enables us to improve our diagnosis and therapy.

Alopecia Areata in the War Wounded from Radiography.—Frenkel saw in 1917 a small epidemic of false alopecia areata among subjects who had been wounded in the eyes, some of which had required enucleation. In every case the first appearance of the disease was in the occipital region, and the spread was rapid, so that within a short interval the space denuded was as large as the palm. In but one of the cases was the patch centrally located; in every other case it was on the side of the wounded eye. The author relates briefly eleven case histories. In six patients enucleation was required. At first the association with radiography was not entertained, although in every case radiographs had been taken. There had been no x-ray dermatitis, and the alopecia could be termed reflex or neuropathic. But why should this particular group of eye wounds lead to alopecia (for many other radiographs of heads were made at the same time)? There was an interval of nearly two months between the shedding of hair and its first reappearance.

La Presse Médicale.

March 7, 1918.

Cavitary Images in Pulmonary Tuberculosis.—Mantoux and Maingot reach the following conclusions: In addition to the classic image described by Bouchard two other types of radiograph may be isolated. One of these suggests the porosity of a loaf of bread, while the other, with greater regularity, resembles the bee's comb. These two forms occur jointly in about one case in seven of open pulmonary tuberculosis. The crumb type is more common than the comb type. Neither has yet been encountered in closed tuberculosis, although 250 cases were investigated. When this kind of radiograph is in evidence physical exploration has demonstrated the presence of cavities in four-fifths of the cases. In autopsies upon these cases one constantly finds minute cavities, and others of medium dimensions. The authors are as yet unable to state whether the new finds are pathognomic of consumption.

A Practical Treatment for Gonorrhea.—Chevallier has already made public a method for treating gonorrhea in wage-earning men without interruption of business. Since then Renault, a specialist of great experience, has conferred with him personally in regard to the expediency of the plan with a view of bringing it

to the attention of the general practitioner. Gonorrhea should not be a disease for the specialist, for its incidence is much too great. One might as well think of specialists for typhoid fever and pneumonia. The author's method of antiseptic irrigation, according to Renault, cannot cure chronic infectious urethritis. This is partly true, for it does not cure them all. When it fails one thinks of a specialist's services, but these may not be available for one or another reason. In these cases Renault and others believe in the efficiency of sandalwood, and the author also prescribes this drug in combination with salol and urotropin. In addition to the local and internal antiseptics the author mentions diet, but has no special recommendations to make. Carle never saw a case made worse by condiments or asparagus. The "therapeutic continence" of the patient often yields when he is nearly cured. The physician must insist on two months added continence after cessation of the discharge. There is often a justified suspicion as to the reason for the virtue or continence of young men. In some circles the result of coitus is looked upon as the test for recovery without any regard for the welfare of society.

Le Progrès Medical.

March 16, 1918.

Somnambulism in Hysteria and Epilepsy.—Bernheim mentions the great frequency of somnambulism in hysteria. Crises of the latter suppress the inhibitory faculties and exalt the passive faculty of imagination. Some of the phenomena of the latter are seen during major attacks, when the patient enacts her thoughts. Somnambulism is not *per se* an automatic act, but the result of autosuggestion. After having been violated a hysterical girl may reenact the whole scene in a hysterical paroxysm, reproducing her struggles and cries for aid. But these dramatic acts are usually replaced by simple dream states in which the patient performs simple automatic acts, in the course of which she rises, dresses, makes her toilet, opens the door, walks in the garden, etc., and after a while returns to bed with complete amnesia. While somnambulist acts may stand in close opposition to crises they also occur in interval periods. As a matter of fact, however, most somnambulism occurs in subjects who never have hysterical crises and conversely most hysterical women are not sleep walkers. In the epileptic somnambulism is most often seen after *petit mal* in some form. Under such circumstances somnambulism is not an epileptic equivalent but a postepileptic phenomenon, a dream suggestion in action, and we also see, as is well known, dream states without action. The same phenomena may occur in interval periods, although by some they would be classed as equivalents. Maudsley even regarded certain attacks of *petit mal* as enacted dreams. Somnambulist actions in epilepsy may be of a criminal type. A newly married epileptic arose in the night and beat his wife. The question of hallucinations naturally arises in this connection. In a similar case a husband had dreamed of his wife's infidelity. The author believes in the autonomy of somnambulism as a condition which complicates various mental states, and is visible at times in true psychoses.

The Briey Iron Basin has been regarded as one of the motives for German conquest but the Germans seem to have found it a disappointment. Apparently it will be cheaper in the end to get iron from Spain and Sweden. The iron and steel masters of Germany regard it as poor business to annex the Basin to no further end than post bellum resentment.—*La Presse Médicale*.

The Clothing Scarcity in Germany.—A trade in second-hand clothing has sprung up and the government is paying a premium to dealers. Every citizen is asked to keep but two suits of clothing for personal use and sell the surplus if any. Parents and relatives of dead soldiers have been requested to dispose of the habiliments of the latter. At the battle front there is a salvage corps, the members of which collect the clothing of dead soldiers in the darkness of night. These uniforms are then furnished up for new soldiers.—*La Presse Médicale*.

Book Reviews.

HEART AND BLOOD VESSELS. By **DR. SATTERTHWAITHE, A.B., M.D., LL.D., Sc.D.**, Consulting Physician to the Post-Graduate, Orthopedic, Manhattan State, and Babies Hospitals; Fellow of the American College of Physicians; Member American Congress of Internal Medicine, American Therapeutic Society, American Medical Association, Harvey Society, New York State and County Medical Societies; Fellow of the New York Academy of Medicine; Member Association of Military Surgeons of the United States; Society of Medical Jurisprudence; Life Member of the New York Pathological Society; Honorary Member of the Medical and Surgical Society of Washington, D. C. New York: Lemcke and Buechner, 1918.

THIS volume is to some extent a regrouped and revised edition of two works by Dr. Satterthwaite, one issued in 1905 and the other in 1913. Both dealt with different phases of heart disease. In the present volume various matters in connection with the heart and circulation which were mentioned only briefly or not at all in the former books, but which have come into prominence within recent years, have been considered at length. Some subjects which appeared in the previous books have been omitted in the one before us. The object of the author has been to produce a work which fully meets the needs of the practising physician, and it is written in clear, concise language. The scheme of arrangement followed is good. Especial notice may be drawn to the chapters on Graves' disease and the internal secretions, and the summary of the author at the end of the chapter expresses the views as to diagnosis and treatment of one who is well qualified to speak with authority on any disease in which the heart is more or less directly involved. The chapter on the internal secretions and the heart is likewise deserving of close attention, and it is pointed out that animal extracts have produced therapeutic results which were not attainable prior to their introduction.

Stress is laid on the efficacy in many forms of heart disease of hygienic and dietetic treatment. Dr. Satterthwaite has a good word to say for the Karel treatment, but draws attention to the fact that in cardiac diseases the amount of food should be carefully regulated and adapted to individual needs. The intake of carbohydrates and of red meat should be diminished, otherwise stomacic and intestinal antifermentatives will probably have to be in regular use. Overeating after middle age has been reached is to be deprecated. Neither coffee nor tea should be taken unless in weak infusions and in small quantities. Exercise is recommended for the treatment of what is known as the "irritable heart." The chapter on drug therapy is an excellent exposition of the present day practice in this regard. The chapter on cardiac surgery was contributed by Dr. W. Wayne Babcock.

Dr. Satterthwaite has brought out an eminently practical and valuable work on diseases of the heart and blood vessels, and one which may be accepted as a safe guide to the general practitioner in his management of these affections.

MANUAL OF SPLINTS AND APPLIANCES FOR THE MEDICAL DEPARTMENT OF THE UNITED STATES ARMY. Report of a Board Convened for the Purpose of Standardizing Certain Medical Department Supplies. Lieut.-Col. WILLIAM L. KELLER, M.C.; Major ROBERT B. OSGOOD, M.R.C.; Major ALEXANDER LAMBERT, M.R.C.; Major JOSEPH A. BLAKE, M.R.C.; Captain W. S. BAER, M.R.C., and Captain NATHANIEL ALLISON, M.R.C. Price, 75 cents. New York: Oxford University Press, 1917.

THIS book of 208 pages embodies the report of a committee appointed by Major-General Pershing, whose membership is noted above, "for the purpose of investigating and reporting upon the advisability of standardizing certain appliances to be used by the Medical Department." The manual describes and illustrates the splints, splint materials, and other appliances that have been found most useful at the front for the immediate treatment and transport of fracture cases, and a number of appliances, such as the Balkan and Blake frames, that are used in the treatment of

these cases at the base hospitals. Individual splints are described in detail and also the indications for their use and the methods of applying them. The descriptions, together with the illustrations, give such a clear idea of the value, indications for and method of applying each type of splint that even the man who has had but comparatively little experience in the handling of fractures should soon become reasonably adept in their application.

This manual is to be distributed to all United States Army Medical Officers here and abroad, and it should be of very great value to all in civil practice who may be called upon to treat fracture cases either in an emergency or as part of their regular practice.

LA PROTHÈSE DU MEMBRE INFÉRIEUR. Par le Dr. F. MARTIN. Price, 5 Francs. Paris: Masson & Cie., 1918.

THIS work is limited wholly to a consideration of prosthesis. Among the numerous illustrations are cinema films showing the mode of progression of one-legged men with prosthesis of different kinds. Provisional prosthesis receives attention. Much space is devoted to American artificial limbs (legs and feet), including those of Marek (Marks?), Frees, Hanger, Palco, Rolwey, Drapier, etc. The only other limbs to be described in detail are those of Belgian make. The subject matter is eminently technical. A preface to the book is supplied by Depage, the distinguished Belgian surgeon.

DISEASES OF THE DIGESTIVE ORGANS. With Special Reference to Their Diagnosis and Treatment. By CHARLES D. AARON, Sc.D., M.D. Professor of Gastroenterology in the Detroit College of Medicine and Surgery; Consulting Gastroenterologist to Harper Hospital. Second Edition, Thoroughly Revised. Price, \$7.00. Philadelphia and New York: Lea & Febiger, 1918.

THE first edition of this work (not to be confounded with the author's monograph on Diseases of the Stomach) appeared in 1915. Three new chapters are added, the subjects respectively being duodenal diagnosis and treatment, intestinal stasis, including the surgeon's viewpoint, and gas producing affections. The success of the work, in the presence of so much competition, is due in part to its eminently practical character—in this respect it is a typical American textbook—and also perhaps to the complete subdivision of the subject matter into general and special chapters, which virtually makes of it two books in one.

AN EPITOME OF MENTAL DISORDERS. A Practical Guide to Etiology, Diagnosis, and Treatment. For Practitioners, Asylum, and R.A.M.C. Medical Officers. By E. FRYER BALLARD, M.B., B.S. (Lond.), Capt. R.A.M.C. (T.), Medical Officer in Charge of the Observation and Mental Blocks, Second Eastern General Hospital (T.F.), Brighton; Sometime Assistant Medical Officer Somerset County Asylum, Wells; Member of the Medico-Psychological Association of Great Britain and Ireland. Price, \$2.25 net. Philadelphia: P. Blakiston's Son and Co., 1917.

THIS book describes mental disease from a symptomatological aspect, but with no effort to understand the symptoms. The writer's classification is poor: hereditary, nonhereditary, and organic. Many obsolete or obsolescent terms are used: "insanity," "lunacy," "amentia agitata," and "persecutory hypochondria." The style is often inexact: divertibility is given as the exact opposite of suggestibility, a precox is "cleverly violent," or shows "degraded conduct." Unwarranted generalizations appear, e.g. that altruists are immune and egoists prone to mental disease. The bromides and early marriage are advised in unstable conditions at puberty, drugging for mania, and chloral hydrate and cannabis indica for dementia precox. The account of the latter condition, by the way, contains much to which exception might be made, e.g. that it is "due to chronic intoxication in degenerate persons," and that "quiet, reserved, egotistical adolescents are chiefly attacked." The writer admits that he is not qualified to discuss psychoanalysis, and then criticizes it adversely. The chapter on shell-shock is the best in the book, but subsequent studies of this subject have automatically rendered it out of date. Altogether this book bears few impresses of the twentieth century.

Society Reports.

AMERICAN MEDICAL ASSOCIATION.

Sixty-ninth Annual Meeting, Held in Chicago, June 10-15, 1918.

HOUSE OF DELEGATES.

First Day—Monday, June 10.

THE House of Delegates was called to order by the Speaker of the House, Dr. Hubert Work of Denver, Col.

Report of the Council on Health and Public Instruction.—Dr. FRANK BILLINGS of Chicago presented this report. He stated that the work of the Council on Health and Public Instruction, like all our other national activities, had been greatly reduced during the past year on account of war conditions. This was partly due to the fact that the entire membership of this Council was actively engaged in public service. Nevertheless, the Council office at the headquarters building in Chicago had been maintained and operated continuously and the routine work had been carried on. Owing to existing conditions and the absorption of the public mind in other topics, it had not been considered advisable to undertake any new activities or the development of any new line of work for the present. As soon as the war was over the Council would resume its function of public education and stimulation of interest in health topics, public health legislation, etc., with the expectation of finding a public sentiment in favor of organized, concerted, and constructive public health work resulting from the educational influence of our military activities greater than had hitherto been possible. The demonstration on a large scale of the effectiveness of modern preventive medicine which had been going on in our camps could not fail to have a marked influence on public sentiment. The entrance into the service of nearly 20,000 physicians as officers of the Medical Reserve Corps would insure in the future a degree of discipline and cooperation in the medical profession that had hitherto been impossible. The Council anticipated a degree of public interest and of constructive effort along public health lines following the war such as had never before been possible in this country. To meet this situation it was more than ever necessary that the organized medical profession should be represented in this field by a permanent board capable of carrying on a definite constructive policy, looking toward the development of the largest amount of cooperation between the organized medical profession on the one hand and the general public on the other. In spite of the handicaps of the war condition the Council had printed and distributed from May 1, 1917, to April 1, 1918, a total of 204,500 pamphlets on public health subjects, besides having replied to many thousands of requests for information.

Reports of Subcommittees of the Council on Health and Public Instruction.—The *Committee on Cooperation with the National Educational Association* reported an increased interest in the various subjects of their committee program. About 8,000 copies of their third report, entitled "Health Charts," had been distributed. The Elizabeth McCormick Memorial Fund of Chicago had made available \$2,000 for the printing of the health chart sets. The Joint Committee approved the proposed plan for the printing of a fourth pamphlet report to be called "Health Improvement in Rural Schools." This would give information regarding the best health work that was being carried out at the present time in the rural schools of the country. Among other activities undertaken under the personal direction of the Chairman of the Committee, Dr. R. W. Corwin, were the following: In southern Colorado they had kept up the protection of the teeth, eyes, and health of the school children in the rural schools. In the coal camps, an eye, ear, nose, and throat specialist had been examining and treating the school children of these schools. A dentist and a special nurse were at work among the school children of the camps, treating and repairing teeth and teaching mouth hygiene. At these camps visiting nurses were working who devoted their entire time to teaching hygiene and sanitation in the homes of the miners. This work was having a decidedly beneficial

effect on the health of the community and did much to improve the schools. Owing to the importance and timeliness of first aid work, they were continuing classes in camps and schools. The importance of architecture of schoolhouses was not being lost sight of—and whenever possible they spoke of the importance of properly constructed schoolhouses.

The Committee on Women's and Children's Welfare reported that during the past year the work of this committee had been largely advisory and cooperative, instead of initiative. This had been necessary because of the lack of appropriation and the absence of the majority of the members of the Council. One new feature of the work had been to get the various state fair boards to make provisions for a department of child welfare. The effort had met with a gracious response in every instance and a number had already established permanent departments. At one fair alone 500 babies were measured and scored. It had been possible for the Committee to come into contact with, and help directly, the plans for child welfare in the women's clubs of the country. In that capacity they had submitted two lines of work closely allied with the work of the American Medical Association, namely, insistence on adequate vital statistics laws and developments and furtherance of baby health conferences. In response to a summons from the Children's Bureau they had met in conference with that body at Washington, D. C., March 14 and 15, to discuss the plans for the children's year. As these plans were being executed by the National Council of Defense with the assistance of the General Federation of Women's Clubs, they offered a far-reaching field for cooperation. The American Medical Association Baby Welfare Charts, Save the Babies pamphlets, and Anthropometric Tables were especially in demand. If the funds were available an unlimited supply of material from this committee would be demanded. It was a source of keen regret that they were unable to meet this demand.

President's Address.—Dr. CHARLES H. MAYO of Rochester, Minn., made this address, in which he said, in part, that he was very glad to meet the members of the House of Delegates. These were momentous times. Never had such opportunities for work been presented to the medical profession as at the present time. The war could not be carried on if it were not for the medical profession. Through its proper organization it was possible to obtain great results in wholesale form. The high position in the Army which the medical profession was now occupying had not been reached without a great deal of trouble. For a long time the medical profession had not been recognized by the Army, the engineers having been given the first place. At first the medical man had been employed as a contract surgeon; he was not an officer, he had no epaulettes, and he was not even saluted. The progress made by the doctor had been certain, but very slow. The medical profession had never acted as a harmonious body, and while great work had been accomplished by various units of the profession, these had always acted separately, often as though in competition one with the other. Even now the activities of the medical profession were being carried out by many units under different Government departments. Under the Treasury Department there was the Public Health Service; under the Department of Labor, the Children's Welfare Bureau; under the Department of the Interior, the care of the insane. If it were possible to coordinate those various activities we could have a wonderful National Board of Health. In Europe the medical was the best maintained governmental organization. It had been our custom in the past to let personalities between individuals or groups of individuals stand in the way of efficient organization of the medical profession, and for that reason it was not occupying the position to which it was entitled. In other words, it was due to petty personalities and jealousies that the medical profession was occupying a so-called fourth-grade position. The world, however, was beginning to realize the work which had been done by the American Medical Association, which consisted of 83,000 men. The work being done was great and should not be belittled by anything within the organization which might divide us. Dr. Mayo gave the names of a number of men prominent in the American Medical Association who were now in the service

, and said that nobody in the Association was so full of his duty.

Secretary.—Dr. ALEXANDER CRAIG of this report, which showed that the

membership of the American Medical Association on May 1, 1917, was 44,010; on May 1, 1918, it was 44,715, a net increase of 705 members for the year. This report contained the record of the *ad interim* appointment of committees to meet the war situation. These committees were appointed in response to the request of the War Department for the active and vigorous cooperation of the American Medical Association and were given full power to act in conjunction with the Provost Marshal General. On this committee Dr. M. L. Harris of Chicago, Dr. Hubert Work of Denver, and Dr. J. E. McKnight of Hartford, Conn., were appointed. Later, Dr. A. R. Mitchell of Lincoln, Neb., was appointed to fill the vacancy caused by Dr. McKnight's death, and the President of the Association and the editor of the *Journal* were added to this committee, through which all the facilities of the Association were placed at the disposal of the War Department. This meant that all the data with reference to the student record, school of graduation, licenses held, hospital service, and practice of medicine of every member of the medical profession in the United States were made available for the War Department. Since the beginning of the war the Association had received almost daily lists of names of those making application for commission in the Medical Reserve Corps concerning which information was desired, and a corps of specially trained clerks had looked up this information and transmitted it to the Surgeon-General's office. This had involved an immense amount of work. A memorial was presented to Congress on January 11, signed by the officers of the Association and the House of Delegates, protesting against the surtax of 8 per cent. on incomes in excess of \$6,000 of all professional men. Copies of these resolutions were transmitted to the Vice-President of the United States, the presiding officer of the Senate, and to the Speaker of the House of Representatives.

Report of the Board of Trustees.—Dr. THOMAS McDAVITT of St. Paul submitted this report, which stated that, contrary to expectations, the year had been a successful one for the Association. Instead of a falling off in subscribers to the *Journal*, there was an actual increase in the circulation, the number of subscribers and Fellows on January 1, 1917, being 65,661; on January 1, 1918, 67,315. The revenue derived from the *Journal* for the past year, that was, for dues and subscriptions, as shown by the auditor's report, was \$318,487.25. Contrary to the predictions of last year, there was also an increase in the receipts from advertising during the year amounting to \$35,000. The fundamental rule controlling advertising was that no proprietary or controlled medicine should be advertised unless it had been investigated by the Council on Pharmacy and Chemistry and accepted for "New and Nonofficial Remedies." The same general principle applied to other articles advertised, that was, the product advertised must be an honest one, and the claims made for it must not be exaggerated. The "Cooperative Medical Advertising Bureau" was giving satisfaction and it was appreciated as a good thing by the various State journals. The *American Journal of Diseases of Children* seemed to be giving satisfaction, at least if judged by the circulation, which was now 2,415; there had, however, been a small loss on this publication last year. The same thing applied to *The Archives of Internal Medicine*, that was, that while there had been an increase in the circulation over the preceding year, the financial loss had been greater than for the year 1917. The Board of Trustees was considering the question of either asking the Editorial Board of the *Archives* to reduce the number of pages or increase the price to \$5 a year. The "Propaganda Department" was cooperating with and advising advertisement vigilance committees, associations of advertisers and advertising managers of various magazines and newspapers with the result that those who were behind the scene appreciated that great improvements were taking place in regard to the advertising standards of these publications. The number of schools and colleges that devoted a certain amount of time each session to the economic, sociological, and health phases of the patent medicine

evil continued to increase. The Educational Posters prepared by the department were becoming widely used in such work. The Council on Pharmacy and Chemistry found its work influenced by the war. Since the war started, no new synthetics or preparations of any kind had been submitted from Germany. Meanwhile radical changes had been taking place in this country. A large number of synthetics for which we formerly depended entirely on Germany were now being manufactured in increasing quantities by American concerns. Four concerns were now making arsphenamine and such products as atophan, veronal, novocaine, phenol, and phenol derivatives. To protect both the public and the profession, as well as to encourage the American manufacture of synthetics, the Council and the Laboratory had willingly investigated the quality of these substitutes for foreign made goods, and when they had been found satisfactory—which has been the case in practically every instance—had accepted them for "New and Nonofficial Remedies." Certain members of the Council had been cooperating with the Federal Trade Commission in solving the problem connected with licensing manufacturers to make certain products hitherto controlled by German patents. At the request of the head of the division of supplies in the Surgeon-General's Office, the Committee on Therapeutic Research and Useful Drugs of the Council held a meeting in Chicago, April 26 and 27, to investigate and make recommendations regarding deletions from, and additions to, the list of drug supplies for the Army. Constituted as this committee was it was thoroughly competent to do this work, and they believed it had been appreciated by the Surgeon-General. The "Committee on Scientific Research" which, in the curtailment of expenses, it was found necessary to discontinue in 1914, the Board of Trustees had felt justified in reestablishing. The newly constituted committee consisted of: Dr. Ludvig Hektoen, Professor of Pathology at Rush Medical College, Chicago; Dr. G. N. Stewart, Professor of Experimental Medicine, Western Reserve University, Cleveland; Dr. A. W. Hewlett, Professor of Medicine, Leland Stanford Jr. University, Berkeley, Cal.; Col. F. F. Russell, Surgeon-General's Office, Washington, D. C.; J. W. Churchman, Professor of Surgery, Yale University, New Haven, Conn., and Herbert Charles Moffitt, Dean and Professor of Medicine, University of California Medical School. This report also included a record of lawsuits in which the Association had been involved and showed what disposition was made of such lawsuits. The long mooted question of whether a corporation not for profit might hold its annual meeting outside of the State of Illinois for the election of its Trustees had finally been settled by a decision of the Supreme Court in favor of the Association. The Supreme Court also sustained the by-laws of the Association, which fixed the method of electing delegates to the House of Delegates and the election of the Trustees by the House of Delegates instead of the membership at large. In reviewing the part taken by the Association in war work, the report stated that in certain quarters the belief prevailed that the Association had not made use of its opportunities or rendered to the Government the service of which it was capable. A brief survey of the work done would dispel any such impression. Since the beginning of the war the Association officers had answered, both by letter and by publication, thousands of questions relative to the service, relieving the offices of the Surgeon Generals of the army and navy of this burden. The Association had printed and sent out a total of 200,000 application forms. It had sent a personal appeal to every physician under 55 years of age and to those who did not answer a second letter was sent. In addition to its effort to increase the Medical Reserve Corps, the Association's plant had printed a large amount of material without cost to the Government. In connection with this point several letters from the Surgeon General's office expressing appreciation of the service rendered by the Association were submitted.

Treasurer's Report.—This report was submitted as an addenda to the Trustees' Report and included the auditor's report. It showed that the surplus of the Association at the beginning of the year amounted to \$382,135.69 and the surplus at the end of the year amounted to \$423,433.87, an increase of \$41,298.18.

Major E. Rist of France was introduced to the mem-

bers of the House of Delegates by the presiding officer, who referred to Major Rist as the Osler of France. Major Rist said, in part, that it gave him great pleasure to have been able to attend the meeting of the House of Delegates of the American Medical Association. He was an old friend and student of the Association. He praised the spirit of association existing among the medical profession in the United States and expressed the hope that now that so many of the American medical men were going over to France the ties uniting the two peoples would be strengthened. He praised the American Medical Association for its work in raising the standard of medical education in this country, and expressed the opinion that the medical education of the United States was the model of the world. The entrance requirements by medical schools in this country were the highest in the world. The United States were also leading the world in public health. He hoped that France would be able to follow the high spirit of association which was existing here in the medical profession and which had accomplished such great work. (Cheers of "Victory" followed this address.)

Report of the Judicial Council.—Dr. ALEXANDER LAMBERT submitted this report, which stated that there had been submitted to the Judicial Council by the president of the University of Minnesota a contract asking for an opinion whether or not the adoption of this agreement would be contrary to the standards and code of medical ethics of the American Medical Association. The agreement was made between E. C. Kendall, party of the first part, William J. Mayo and Charles H. Mayo, parties of the second part, and University of Minnesota, party of the third part. This agreement stated that E. C. Kendall, an employee, working under the auspices of Drs. William J. and Charles H. Mayo had discovered an agent "Thyroxin" for the treatment of disease and had applied for letters patent of the United States thereon and intended to apply for letters patent in foreign countries. E. C. Kendall agreed to give all patent rights and titles and trade name to the University of Minnesota and the Drs. Mayo agreed to give all their rights, titles, etc., in this same medical discovery to the same university. The university agreed to do all the selling and exploiting of the medical discovery and agreed to give 10 per cent. of the returns to E. C. Kendall and to cover in to the present Mayo foundation fund of the university the remainder and use them for scientific investigations and for the furtherance of scientific study. From time immemorial it had been unethical for members of the American medical profession to patent medical discoveries and use the proceeds for gain. The Judicial Council was of the opinion that the same standard which applied to individuals must also be conformed to by partnership companies and corporations of which a physician was a member. It was therefore the opinion of the Judicial Council that it would be unethical to consummate this agreement. It would be unethical for the University of Minnesota because it would be unethical for the members of its medical faculty to agree to accept a patent and patent rights which the university proposed to use for commercial gain, just as much so as it would be unethical for these medical men individually to patent or accept a patent of a medical discovery and exploit it for personal gain. It would be unethical for the Drs. Mayo on their part to consummate this agreement for they would be patenting a medical discovery and using the commercial proceeds therefrom to increase a fund given by them to the university and it would still be unethical for them to patent the medical discovery and turn over to a third party the commercial exploitation thereof.

Report of the Council on Medical Education.—Dr. H. D. ARNOLD of Boston submitted this report, in which he reviewed briefly the progress that had been made during the past fourteen years in improving the character of medical education in this country. The advantages in this country at present were the higher and better supervised entrance requirements; larger staffs of well qualified, full-time laboratory teachers; closer relationships with large and well conducted hospitals; and the use of the more modern methods of practical and clinical teaching. Commercialism has been practically eliminated from medical teaching and only a few

seriously low grade medical schools continued to exist. Now, as shown in one of the charts, 80 per cent. of the medical schools were requiring for admission two years of collegiate work; the majority had teaching relationships with one or more hospitals in which clinical material was abundant and being used in accordance with the latest methods of teaching. Of all the improvements enumerated the one of greatest importance had been the increase in entrance requirements. With the present standards America need no longer apologize when the subject of medical education was broached. It was gratifying to know that the reforms in American medical education were so nearly completed before this country was finally drawn into the world war. As a consequence the majority of students graduating in the last several years had received a medical training equal to the best obtainable anywhere. Furthermore, it was the recent graduates that had entered the government service in larger proportions, and who would be responsible for the medical care of our American soldiers and sailors. It was a matter of congratulation therefore that those fighting for the preservation of America and American ideals would have as skilled medical care as those of the opposing armies. This could not have been said had it not been for the energetic campaign of the last fourteen years to improve medical education. The report showed that there was no dearth of physicians, but an increased demand, and there was also a demand for better, not lower, education. Even for army purposes the demand was not so much for ordinary physicians and surgeons as for those of highly technical and special training. Emphatically, therefore, the present demand did not call for a lowering of educational standards, but for the maintenance of present entrance requirements, for further improvements in laboratory and clinical equipment, and particularly for improved methods of teaching in all the medical schools. It was only by maintaining these fair standards that the demand would be supplied, since in the best medical schools the number of graduates had steadily increased for the last five years, while the number graduating each year from the lower grade medical colleges had steadily decreased. One result of the campaign for improved medical education had been that a generous financial support had been provided for medical schools, either from state appropriations or private sources. In providing funds it appeared that medical schools for negro students had been largely overlooked, although their need for such support was proportionately greater than for medical schools in general. Now they not only lacked this financial aid, but also their income from student fees had been considerably reduced as a result of the general adoption of higher entrance requirements. For these reasons largely, medical schools for negroes had not been able to keep pace with the rapid improvements made in other medical schools. There were about eleven million negroes in the United States and only four negro medical schools. One of these was in Class A, two in Class B, and two in Class C. Since 1904, the Council had had as one of its regular functions, the collection and tabulation of statistics which were published in the State Board Number of the *Journal* in April each year. These statistics had had a large influence in the improvement of both medical education and medical licensure. The various improvements brought about in medical licensure during the last fourteen years were set forth in one of the tables presented. Next to the improvement in the standards of preliminary education the greatest increase was in the number of states (now 37) which were refusing to recognize low grade colleges. The greatest needs at present were that adoption of the requirement of the hospital interne year; a general adoption of the two years of premedical college work, and—a matter of extreme importance—a more general and larger use of practical laboratory and clinical tests in the state licensing examinations. Recognition of the National Board of Medical Examiners, which was organized in 1915, and which had received the recognition of the Association, had now been granted recognition by eleven states and holders of its certificates would be registered without further examination in Colorado, Delaware, Idaho, Kentucky, Maryland, New Hamp-

13, North Dakota, Pennsylvania, Mont. At the meeting of the Council and the Association of American Medical Students in Chicago, in February, 1918, the following premedical requirements which

was unanimously adopted was as follows: "(a) For admission to the two-year premedical college course, students shall have completed a four-year course of at least fourteen units (fifteen after Jan. 1, 1920) in a standard accredited high school or other institution of standard secondary school grade, or have the equivalent as demonstrated by examinations conducted by the College Entrance Examination Board, or by the authorized examiner of a standard college or university which has been approved by the Council on Medical Education. Unless all the entrance units are obtained by examination, a detailed statement of attendance at the secondary school, and a transcript of the student's work, should be kept on file by the college authorities. This evidence of actual attendance at the secondary schools should be obtained, no matter whether the student is admitted to the freshman or to higher classes. (b) Credits for admission to the premedical college course may be granted for the subjects shown in an appended list and for any other subject counted by a standard accredited high school as a part of the requirements for its diploma. The requirements of the premedical college course were as follows: (c) Beginning Jan. 1, 1918, the minimum requirement for admission to acceptable medical schools, in addition to the high school work specified above, will be sixty semester hours of collegiate work, extending through two years, of thirty-two weeks each, exclusive of holidays, in a college approved by the Council on Medical Education. The subjects included chemistry, physics, biology, English, composition and literature. Certain other subjects were also urged, as French or German, advanced botany, psychology, algebra, and trigonometry, and additional courses in chemistry. The reorganization of medical education had now advanced to a point where another general classification of medical schools was essential and should be made as soon as circumstances would permit. Aside from the necessity of this revision on general grounds, it was now of special importance in connection with the recognition of medical schools by the Federal service under the regulations of the selective service law. Since the effect of these regulations would be the closure of such institutions as were not considered "well recognized," because of the drafting of their students if the war continued any length of time, it was particularly important that the Council's classification should be made in strict justice and that it be made on the actual conditions now existing in the schools. A new schedule for the grading of medical schools had been formulated, and was included in the report. A scheme was also outlined for continuous sessions in medical schools which suggested that for the duration of the war each year be divided into three periods of four months each, these sessions beginning in October, February, and July of each year. It was shown that the student could enter on the study of medicine at the beginning of any one of these periods and continue for eight successive periods of four months each, at which time he would graduate and enter on an intern service of one calendar year. This would require just four calendar years when he would be ready for active service with the army. It was argued that by the adoption of this or some similar scheme the summer periods heretofore looked on as vacation time would be utilized; the extensive teaching plants would be kept in continuous operation, and students would be graduated from nine to twelve months earlier than under the methods heretofore prevailing. Under this scheme the present junior class would be graduated four months earlier; the present sophomore class would be graduated eight months earlier, and the present freshman class would be graduated a year earlier than under the former method. It was argued also that since there would be no vacations for the boys in the trenches, or for the medical officers in the service, there appeared to be no reason why medical students should expect a vacation. The Council and the information it had collected had rendered important services to the Government in giving the Government access to its files, both those of

the Medical Students' Register and its files of information in regard to medical colleges, and standards of preliminary and medical education.

Report of Council on Scientific Assembly.—Dr. E. S. Judd of Rochester, Minn., presented this report, which emphasized what had been said last year with regard to the number of section meetings in the Scientific Assembly, namely, that too many section meetings were held at the same time. There was no question of this. They had been accused of devoting too much time to scientific work and too little to social enjoyment and getting acquainted with one another. The Council was of the opinion that a more effective distribution of time would be presented if the sections were limited to one meeting a day. The Scientific Assembly ought to be so conducted that a man would not think he was neglecting the section in which he had an especial interest when he took time to keep in touch with what was being done in other sections or to meet other physicians outside the sections. It should be emphasized that the Scientific Assembly of the American Medical Association was an entity and that the sections were merely parts of the whole. Allegiance to a particular section was desirable. It had been and was an important factor in developing scientific work. The Council on Scientific Assembly had been successful in securing cooperation between the sections and arranging for a continuation of the program throughout Friday. If the three full days were used for section meetings, it would be very easy to carry out the suggestion that the number of these meetings being held at the same time should not be more than eight.

Report of the War Committee of the American Medical Association.—Dr. HUBERT WORK submitted this report. He stated that this committee, constituted by action of the Board of Trustees at its annual meeting, held October 19, 1917, and ratified by a postal vote of the House of Delegates, as soon as it was empowered proceeded to Washington, where it obtained an interview with the Provost Marshal General and his associates, and formally tendered the services of the American Medical Association to that office for such services as the Association could render in the creation of medical advisory boards. The committee, at the request of the Provost Marshal General, submitted a working proposition for the formation and supervision of these boards, which was approved and afterward adopted. The Committee then returned to Chicago and arranged a meeting with the representatives of the Committee on States Activities, General Medical Board, Advisory Commission and Council of National Defense. These representatives, together with the Committee of the American Medical Association, formed a joint committee to which were added Dr. Edward Martin of Philadelphia and the Secretary of the American Medical Association, who became the secretary of the committee. They then proceeded to the organization of the medical advisory boards. More recently they had been actively engaged in securing a future increment to the Medical Reserve Corps. A meeting was held in Chicago, on April 30, at which thirty-eight constituent state associations were represented, and a day was devoted to how the organized medical profession could be utilized effectively for the winning of the war, and specifically how the American Medical Association, its constituent state associations, and their component county societies could assist in enrolling the required increments for the Medical Reserve Corps of the Army and Navy. The secretaries of the state associations returned to the several states with the determination to coordinate the forces of the organized medical profession in their states with other agencies working with similar objects. To determine to what extent the medical profession in various parts of the country had met its responsibility to the Government, the *Journal* for June 1 published a survey or "Honor Roll" of the medical profession of the United States. This showed the important facts regarding each county, and had proved effective in stimulating applications for commissions in the Medical Reserve Corps.

Resolutions.—On behalf of the Medical Society of the District of Columbia special courses for "Practical Nurses" were urged to meet the great demand for nurses occasioned by the war, and which would also allow a person of average means the opportunity to

secure nursing services. Resolutions were offered on behalf of the medical societies of California, Ohio, and other states, to empower the President of the United States, the Secretary of War, and the Surgeon General to appoint women physicians in the Medical Reserve Corps on the same salary and footing as men physicians. The various resolutions praised the achievements, ability, and patriotism of the women physicians. On behalf of the Universal Military League a resolution was offered requesting the enactment of a law requiring universal military service of every man before the right of suffrage was granted to him.

Second Day—Tuesday, June 11.

The morning session was devoted to the reports of the various reference committees on the resolutions which had been offered during the previous session.

The Reference Committee on Rules and Order of Business recommended that Section 3, Chapter 4 of the By-Laws be amended to read: "Provided that the House of Delegates upon a motion of its members could change the time of election of officers, the motion having been made one day in advance and carried by three fourths of the voting delegates." The recommendation was adopted. The Committee further recommended that Section 4 of Chapter 4 of the By-Laws be changed so the words *Speaker* and *Vice-Speaker* be substituted for chairman and vice-chairman. That recommendation was also adopted.

Dr. J. W. SCHERESCHEWSKI, U.S.P.S., as chairman of the Committee of Hygiene and Public Health recommended that the resolution which had been offered on behalf of the Medical Society of the District of Columbia relative to special courses for nurses be adopted, and that a special committee be appointed for that purpose.

Dr. COLLIN of Baltimore wanted to know what the Surgeon General's office was doing on that question and suggested that Dr. McClain, who had been present at the session, be called upon for information. Dr. McClain stated the question had been discussed freely by the nurses themselves and that if a committee appointed by the House of Delegates could assist them in any way they would welcome such aid. He stated that the Surgeon General had opened a school for nurses in connection with the army. Dr. Craig of Chicago suggested that the report of the Committee be accepted, be favorably commended, and be referred to the Council of Public Health and Instruction.

Dr. ALEANDER LAMBERT of New York said that the nursing situation was an acute problem. Not only must there be enough nurses to send across but enough must be left at home. The French and British had to meet the same problem. In Britain this was solved by means of the Nurses' Aids Association, many educated and clever women were attracted to that work; they had soon become proficient and often equaled the trained nurses in caring for the wounded. There had, however, resulted a great deal of friction between the regular nurses and the nurses' aids, and the latter had been frequently placed in the position of scrub women. Educated and intelligent women could learn the technique of caring for wounded quite rapidly. Instead of having all graduate nurses there should be undergraduate nurses as in all hospitals. There were many clever and intelligent women who were eager to help in this war. Instead of being aids they should constitute an Undergraduate Class. Women of college education would be given one year's credit and they could get their diplomas in two instead of three years. The special character of warfare carried on now resulted in the death of many nurses and this deficiency would also have to be met.

Dr. FREDERICK SONDERN of New York said the Committee on Public Hygiene realized that so far as the supply of nurses for the army and the navy was concerned that question was in good hands, the work of the proposed committee would be to handle that question from the civilian's standpoint only.

Dr. KRESS of California moved that the recommendation of the Committee on Hygiene be referred to the Council of Public Health and Instruction, with instructions that special attention be paid to the question of the civil population, and that a sub-committee be ap-

pointed for that purpose. The motion by Dr. Kress was adopted.

Dr. GRAVES of Texas, chairman of the Reference Committee on Legislation, recommended that a resolution be adopted empowering the Surgeons General of the army, navy and public health to employ women physicians in the special fields for which they were fit and that when employed they were to receive the same pay and rank as men in similar positions. That recommendation was adopted.

Dr. WETHERILL of California, chairman of the Committee on Election of Officers, recommended that the War Committee appointed by the Board of Trustees be confirmed, that the work of the propaganda department be endorsed and commended, and that the Board of Trustees be specially commended for having successfully defended the suit which had been brought against the American Medical Association, and further that the entire report, which had been made by the Board of Trustees be adopted. Dr. Wetherill's recommendations were adopted.

Dr. HUMISTON of Illinois, chairman of the Committee on Miscellaneous Business, recommended that the resolution which had been introduced on behalf of the Universal Military League urging the early adoption of a national policy of universal military service for all men, before the right of suffrage would be granted them. The resolution was adopted.

The following resolutions were also adopted upon motions by various members of the House of Delegates: The House of Delegates endorsed the Owen-Dyer bill now before Congress, giving increased rank to medical officers of the army, and urged its early adoption.

That it was to the best interests of the nation that Surgeon General Gorgas should not be retired when he will have reached the retirement age, but that he be retained in active service and in the same capacity and that a copy of that resolution be forwarded to the President of the United States.

That in consideration of the impending emergency a class of undergraduate medical men be established in the army with commissions as high as First Lieutenant, who would not have the authority to practise medicine after the war unless they had met all requirements made by the then existing State boards.

That the American Medical Association calls upon its members to further the cause of the war by confining their prescriptions to products owned and manufactured by loyal citizens of the United States wherever the welfare of the patient would permit it.

OPENING MEETING.

Tuesday Evening, June 11, 1918.

THE PRESIDENT, DR. CHARLES H. MAYO OF ROCHESTER, MINN., IN THE CHAIR.

THE Sixty-ninth Annual Meeting of the American Medical Association was opened by an invocation by the Rev. Dr. John Timothy Stone of Chicago.

Address of Welcome.—Dr. EDWARD W. FIEGENBAUM of Edwardsville, Ill., President of the Illinois State Medical Society, made this address, in which he extended the greetings of that organization and of the medical profession of the State to the Fellows and guests of the Association. He said that the profession of Illinois was not all present this evening. Nearly 2000 of the foremost medical men in Illinois had volunteered in the service of the country, and he had been commissioned to speak for them. Though in body they were over one thousand miles away, in spirit they were here giving us their greeting. They were in the camps and cantonments of this country, in battleships and on transports, on the high seas, in base hospitals, and on the firing lines. Each one was doing his duty by his country in a medical way. They had left families, successful practices, and prominent places in their respective communities. They were eager and anxious to serve the Government. They had left security and were braving sickness and death. "All hail to the medical profession which had laid its all on the altar of its country." It was fitting that the meeting of

Medical Association should hold its meeting in the Centennial year of Illinois, and was preparing to celebrate. The oldest medical school of this State was older than the State. In 1802 George Caldwell landed in Madison County opposite St. Louis and laid the foundation of a medical organization in this State. A little later an attempt was made to register the physicians of this State and this foreshadowed the present complete registration of the physicians of the State. The physicians of those days had upheld the science of medicine at that time to the best of their ability, and from decade to decade after that they were always upholding the welfare of the State. There was no state that had medical laws that were superior to those of Illinois. In the dawning years of the Twentieth Century they had been instrumental in eradicating medical schools not up to the standard, until in this State they had nothing but Class A medical schools. Their last achievement was to get the best medical practice act that had yet been enacted in this country. The medical profession was always laboring to maintain the standard of medical education at all times. This was the foundation upon which they had built and reared this superstructure. They had always been guided by the highest ideals and it was now not only possible but almost an assured probability that these men would make within the confines of this State a medical center of the universe. It was such men as these that had bid him say "welcome" to the State of Illinois.

Address of Welcome.—Dr. CHARLES E. HUMISTON of Chicago made this address in behalf of the Medical Society of Chicago. He said, in part, that Chicago was proud to be the host of such distinguished company. This was the home town of the American Medical Association. There was perhaps no State on the Continent that did not share in this honor, but still the American Medical Association must feel more at home in this State than in any other. The American Medical Association ranked high among scientific organizations of this country. It was the representative medical body of this country to which every reputable physician might belong and to which most reputable physicians did belong. The Nation at this time was depending upon the organized medical profession and in this confidence the Nation would not meet with disappointment. The three thousand members of the Medical Society of the County of Chicago extended their welcome to the Association. Davis, Senn, Finger, Murphy, and others, were here in spirit and bid them welcome. These members who were not here were now engaged in building and preserving the military strength of our beloved country and many had gone to that undiscovered country from whose bourne none returned. We had their example to inspire us to greater endeavor. Dr. Humiston then greeted individually guests from France, from Belgium, from England, Italy, Australia, New Zealand, and Canada, and his greeting was supplemented by enthusiastic applause on the part of the audience. He also extended personal greetings to the representatives of the Army, the Navy, and the Public Health Service.

Introduction of Distinguished Guests.—Dr. MAYO then introduced Surgeon General Gorgas, Surgeon General Braisted, Sir James Mackenzie of London and Edinburgh, Sir William Arbuthnot Lane of London, Major E. Rist of France, Major DeHellen of France, and Lieutenant Colonel Bruce of Canada.

Address.—Honorable FRANK O. LOWDEN, Governor of Illinois, delivered this address. He said, in part, that it was a very great honor which the organization had conferred upon him in permitting him to speak to-night. Never in the history of this country had so distinguished a body of the medical profession been gathered together as was in this hall tonight. It was not only an honor which he appreciated, but one which he coveted because he wanted to say to the American Medical Association that they of Illinois were under great obligation to the Society. In the last eighteen months they had organized their State Health Department and in this work the American Medical Association had cooperated admirably. When they sought to elevate the standard of the society they had their own troubles he understood. If a man got the idea that, if he only went somewhere where the magical

words "medical college" were over the door, he could come out from that place and treat the sick he was against this society. Again some men obtained their license to practice medicine that they might prey on the sick and unfortunate, and those men were against this society. Again he wished to say that it was a great pleasure to admit that this country and the whole civilized world were under obligation to this association for the way it had thrown itself into this war heart and soul. Governor Lowden said he wished to explain to them why it was that American physicians and surgeons had been so keen to appreciate the significance of this colossal conflict which had divided them from German professional men: it was because they had never come under the influence of Kultur; they were still guided by the old fashioned in what they called civilization. Sometimes he thought that we of America as well as those of our Allies did not dwell enough on the contributions which our scientific men had made to civilization. They had taken too much for granted the claims of the autocracy of the Central Empires to what they called Kultur. This new Kultur was borrowed from England. It was the invention of an Englishman and was based on the law of the survival of the fittest. Although that was a biological law, Germany had misapplied it when she brought it into her country. While they all recognized that this was a great law, the survival of the fittest, most people recognized that it did not refer to the moral and spiritual which was in control of the physical laws of the universe. When this idea was imported into Germany it was interpreted to mean not only the survival of the fittest physically but that they should rule the world. They considered moral law as only a foolish thing made to protect weaklings. The strong must rule the earth and to this end they developed the superman. But the rest of the world knew that the law of the survival of the fittest had nothing to do with right and wrong. All the rest of the world knew that moral force, although unseen, was the final arbiter of the universe and therefore Kultur was only a materializing philosophy which was possible only by the exclusion of all other truth; therefore the difference between the physicians of England and Scotland, France, Italy, and America and those of Germany. The physicians of the rest of the world had bowed to the biological truth, but it only meant to them that they were to remove the cause of disease by removing the unfavorable environment of the weak and by lifting up and strengthening the sick and unfortunate, and in that way they gave expression to the modern law. As the Germans applied this law it meant the destruction of the weak and unfortunate and thus made the superman supreme. Thus had Kultur been developed. The physician, in common with the minister of religion, made it his aim to alleviate moral ills and to devise ways and means of making the weak strong morally and physically. In contrast to this the physician of Kultur had no tenderness for humanity, for women, or for the home.

The speaker stated that he was very much interested in the German mathematical accuracy which had computed the value of every man in the service. It had found that a physician was equivalent to five hundred men in the ranks. The American Medical Association was contributing 40,000 physicians, which would by easy mathematical calculation show that it was contributing the equivalent of twenty million men in the ranks. When one considered that that great force was directed by a great genius like Surgeon General Gorgas, who could compute the results, for it was to be remembered that this, the German, was not the first enemy General Gorgas had met. All were mindful of his former achievement in Panama, where his enemy was not the German but the mosquito, but they were both very much alike in that they had the same notion of the rules of civilized warfare and the same disregard of men. The mosquito was no mean enemy to trifle with. General Gorgas did to the mosquito in Panama what the German Army had not done to the French; it drove the French from Panama and the French had so far held the Germans back. But Governor Lowden said that when he spoke of the French it was always France that had delighted the world with their marvelous creations, but the greatest master of romance had

written nothing as thrilling in fiction as the French soldiers had written in fact during the last three years. But to return to German Kultur—German Kultur had appropriated the inventions of the French, the Italians, the English, and the Americans. They vaccinated their men against smallpox by a vaccine discovered by Jenner; they soothed the pain of their wounded by anesthesia discovered by an American; they treated their wounded by antiseptics discovered by an Englishman. Had it not been for the inventions of the other nations, they would not have been able to hold the world at bay these last four years. After referring to the brutality inflicted on women and children, Governor Lowden said if we did not vanquish Kultur it would take the next logical step in its course and it would exterminate the weak, the helpless, the deformed, and would rule the world; it would exterminate the men and reduce the women to slavery. No savage was so dead to everything that pertained to civilization as the exponents of Kultur, and if unconquered it would overshadow and blacken the whole world. If Germany won, the superman of Germany would become the superfiend of the world. After the Germans had devastated and pillaged Belgium their mathematical efficiency had led them to classify the watches they had taken into first, second, and third class and to keep record of the number of spoons taken and the amount of champagne; it was logical that they should keep these things and value them, but they destroyed the cathedrals because every cathedral spire pointing to heaven was a rebuke to their brutality and an act of reproach. The German God of to-day was brought from the dark forests of 2,000 years ago. If we only knew what this war meant we would win it. In the darkest hour a few weeks ago when it seemed that the French and the English would be overwhelmed it was our deepest regret that the American forces were not there in full force. But if the Germans had separated the French and English armies, if they had driven the British Army into the channel, if they annihilated the allied armies, if they came to the gate of New York, we remained indomitable. It was better to die as free men than to live as slaves. In closing, Governor Lowden strongly warned his hearers against being seduced by a treacherous peace, and showed that Russia was more wretched under the peace she had made with Germany than under war conditions.

Post-Graduate Medical School in France.—Dr. MAYO, before introducing the president-elect, stated that it might be of interest to the audience to know that plans were under consideration for the establishment of a great post-graduate medical school in France, which would accommodate 1000 medical officers. This school would be most perfectly equipped and at the end of the war it would be turned over to the medical profession of France as a gift from the medical profession of America.

The Organization of the Medical Profession for War.—Dr. Arthur Dean Bevan then delivered the presidential address (see page 1036).

ELECTION OF OFFICERS.

President, Alexander Lambert, New York.

First Vice-President, William N. Wishard, Indianapolis.

Second Vice-President, Edward Starr Judd, Rochester, Minn.

Third Vice-President, Charles W. Richardson, Washington, D. C.

Fourth Vice-President, J. M. Barlow, Philadelphia.

Secretary, Alexander R. Craig, Chicago.

Treasurer, William Allen Puscy, Chicago.

Speaker of House of Delegates, Hubert Work, Pueblo, Colo.

Vice-Speaker, Dwight H. Murray, Syracuse, N. Y.

Trustees, Frank Billings, Chicago, Wendell C. Phillips, New York, Thomas McDavitt, St. Paul, Chester D. Brown, Danbury, Conn.

Judicial Council, M. L. Harris, Chicago, William S. Thayer, Baltimore.

Council on Health and Public Instruction, John M. Dodson, Chicago, William S. Rankin, Raleigh, N. C.

Council on Medical Education, H. D. Arnold, Boston.

Council on Scientific Assembly, Roger S. Morris, Cincinnati.

Next place of meeting, Atlantic City.

ASSOCIATION OF AMERICAN PHYSICIANS.

Thirty-third Annual Meeting Held at Atlantic City, N. J., May 7 and 8, 1918.

DR. F. H. WILLIAMS OF BOSTON, PRESIDENT.

(Continued from page 1010.)

A Study of the Empyemas at Camp Upton.—Major H. BROOKS, M.R.C., and Major R. L. CECIL, M.R.C., presented this paper. Major Brooks said that Major Cecil had undertaken an extensive study of the laboratory side of the problem. They had had a very virulent type of empyema. The cases were all associated with pneumonia. The disease had also been associated with measles, but not with mumps. The causative germ had been the streptococcus in 50 per cent. of the cases, in the other 50 per cent. the pneumococcus. Cases of pneumococcus empyema had recovered after operative treatment. There were 49 cases of streptococcus empyema with a mortality of 61 per cent. Of four *Streptococcus viridans* cases three died; four mixed infections with streptococcus and pneumococcus, no deaths; of 35 hemolytic streptococcus cases, 22 died. The empyema seemed in each case to be a concomitant infection of the pleural sac. With the entrance into camp of a large contingent of colored troops the percentage of hemolytic streptococcus infections increased. The question arose as to whether this disease was transmitted directly from soldier to soldier, but with very careful isolation of cases there was found to be no diminution of occurrence. Still, the isolation was being carefully maintained. In the bronchial type of infection there was very little cough, very little sputum raised, and very little pleuritic pain. The chief symptom throughout was prostration. The diagnosis was made by aspiration, confirmed by the x-ray findings, and the changes in percussion were an important sign. The exudate in these cases had the appearance of alkaline urine and generally contained streptococci. Pericarditis usually developed early in these cases and was progressive, but there was lack of metastases elsewhere. Of 27 cases that came to autopsy 23 were streptococcus cases. The pulmonary lesion showed interstitial bronchopneumonia of the type described by Cole. Pneumothorax was also present. As regards treatment it had been found that early operations were fatal. It was essential to wait till the pus became cellular in character, when operation could be safely performed.

Dr. H. A. CHRISTIAN of Boston said that in civil practice they had had practically the same experience as had been reported in army cases. Very frequently the streptococcus was the etiological factor. The cases were the interstitial type of bronchopneumonia. Experience showed that fatalities occurred from too early operative interference. Some cases got well with repeated tapplings of the fluid. The pneumonias had a tendency to shift in type and at first they had been much disturbed with atypical forms, until they found that frequently they had to deal with streptococcus.

Dr. E. LIBMAN of New York said that Fraenkel had drawn attention to the fact that during epidemics of grippe the pneumonias and empyemas followed a devious course. During such epidemics it was found that primary empyemas occurred. This form of the disease had been named pleuritis acutissima. The apex had to be watched for accumulation of fluid. Dr. Libman said his experience had been that the x-ray would help in detection of empyema, but that sometimes it failed. This failure occurred when the empyema was localized between the lobes and under the axillæ.

Major W. H. WELCH of Baltimore said that in civil practice streptococcus infections were the most important infections. In regard to these cases there had existed at first a period of great confusion. Investigations were then made by Drs. Zinzer and Dochez which brought out clearly that the streptococcus was the most important cause. At one camp the cases seemed to be due to the *Streptococcus viridans* and it was a question as to what had imparted to this streptococcus these unusual properties. What reasons had played a part in enhancing the virulence of the streptococcus? This was the most important problem today in dealing with infections of soldiers. With universal evidence of the disease spreading within the hospital it was nec-

light one could upon the etiological information as would bear upon the management of the disease. It was of experts should give undivided attention to the solution of the problems. Dr. MacCullum had thrown much light on the problem of the lesion in the lung as seen at autopsy. The pulmonary lesion was frequently so mild as not to be recognized. The infection through the respiratory tract the streptococci made way rapidly to the pleural passages, but no doubt they left one or more small foci of the disease which could be detected on careful examination. This matter was of the utmost importance and could be studied in camps under different conditions to those of civil life. For the proper control of the disease it was necessary to discover exactly what the biological properties of a given streptococcus were. There was no cultural distinction for these different properties. Men all over the country should unite in comparing their investigations so that medical officers should have the necessary knowledge for controlling disease among the troops.

Major R. L. CECIL, M.R.C., spoke about the bacteriological aspect of these cases. In regard to the pneumococcus, cases were found with Type II in the sputum and Type IV in the pleural fluid. Of the streptococcus group four cases had shown non-hemolyzing streptococci. These were recognized as *S. viridans*. Dr. Cecil said he was loath to make a diagnosis of *S. viridans*, as this could be said to be a constant inhabitant of the normal mouth, but upon using blood broth medium the sputum cultures showed absolutely pure growth of this organism. The colonies were typical—small, green, with a very slight zone of hemolysis which did not appear in blood broth cultures. In the types of cases with mixed infection there was a mortality of 60 per cent. Often there was streptococcus in the pleural fluid and pneumococcus in the sputum. Drs. Cole and MacCullum had met with cases of mixed infection in Texas. In regard to sterile empyema there was some confusion as to what was empyema and what simply pleural fluid. Empyema cases had pus cells in the fluid. Some cases showed bacteria in the smears, but cultures on blood agar were negative. Many cases showed localization between the left lung and pericardium and this probably explained the frequency of pericarditis.

Major E. P. JOCELIN, M.R.C., said that of 55 cases operated on seven died. Operations were by simple drainage and no osteotomies were done. Twenty cases died without operation. In many cases several cavities were involved.

Dr. RUFUS COLE of New York said that in the epidemiological view, rather than the viewpoint of complications of pneumonia, the streptococcus empyema was very different from the pneumococcus infection. Things were not as yet very clear about the whole situation. They had to be very accurate about interpreting favorable results of any procedure until considerable conclusive evidence had been obtained and until they could tell whether they were dealing with a frank streptococcus pneumonia or an empyema developing under deep lobar pneumonia. A large group of cases had to be carefully classified and the results of various methods analyzed before one could say that one or other form of treatment was the best. Another important point was the necessity of cooperation between the surgeon and physician following operation. The internist had not completed his whole duty when he had made a diagnosis of empyema and had turned over the case to the surgeon. Often in these cases several pockets of pus were present. Simply putting a knife into the chest would not cure the empyema. Where a second pocket was known to exist extreme care on the part of the internist was necessary.

Experimental Hemochromatosis.—Dr. PEYTON ROUS of New York made this presentation. The pigment seen in cirrhosis of the liver was stated to be derived from the blood. If the activity of the spleen and the liver could be overborne the pigmentation could be controlled. It was sought to do this by experiments on rabbits, which were known to be able to put away a very large quantity of alien blood. Rabbits were transfused and in 3 months there was found to be a considerable siderosis of the spleen and bone marrow, caused by the pigment hemosiderin. This was analogous to the

deposits of hemosiderin in human hemochromatosis. Dr. Rous showed lantern slides illustrating the deposits of hemosiderin in various organs, such as the liver, kidney, spleen, and bone marrow of transfused animals. The siderosis was caused by the breaking down of over-pigmented cells. In the human subject the hemosiderin pigmentation might be secondary to the cirrhosis. The injury to the pancreas in the cases caused death. The pectoral distribution of lesions in hemochromatosis indicated the influence of actinic rays upon the pigment.

Hemosiderin Granules in Cells of the Urine; an Aid to the Diagnosis of Pernicious Anemia and Hemochromatosis.—Dr. Rous read this paper also. It was thought that hemosiderin might be found in the urine. In a soldier of 46 years of age, with lesions of hemochromatosis, the diagnosis between this disease and syphilis was doubtful. There was enlargement of the liver and spleen and a peculiar gray pigmentation of the skin. The urine was found to contain considerable hemosiderin granules. The patient died within 3 months with characteristic signs of hemochromatosis. It was also stated that in eight-tenths of the cases of pernicious anemia hemosiderin granules were found in the urine. Fresh urine should be used for the test.

Dr. E. L. OPIE of St. Louis, Mo., said that the experiment did not explain the etiology of hemochromatosis, but it did account for the pathology. In every essential it seemed clear that the disease had been reproduced by the experimental method. The disease was perhaps due to interstitial inflammation of the pancreas. The cirrhosis of the liver was probably secondary to accumulation of iron pigment in the cells. Had Dr. Rous found any destruction of parenchymatous cells as the result of accumulation of pigment in them? He thought it was difficult to produce cirrhosis of any organ in the lower animals, in which reproduction of parenchyma occurred more readily than it did in the higher animals.

Dr. W. TILESTON of New Haven said that in connection with pigmentation in chronic family jaundice he had recently found in the spleen and liver a hemosiderosis very comparable with that shown by Dr. Rous in the picture. In this case, a patient of 67 years, there was no cirrhosis of the liver.

Dr. P. ROUS said that the animals had not been pushed far enough to get breaking down of the cells. They were now trying to keep the animals longer. The body was found to tolerate hemosiderosis to a remarkable degree, but in the human organism, in cirrhosis, the cells were not flooded with pigment as were those shown in the experiment. One must assume that the liver was in some way prevented from destroying the blood pigment so that hemosiderin would accumulate in the cells.

Mould Infections.—Dr. C. P. EMERSON of Indianapolis read this paper. The patient, a man of 48 years, presented himself for treatment of tuberculosis. He had no toxic symptoms, no asthenia, no secondary anemia. He stated that he had not been able to lie down to sleep for 11 years, on account of asthmatic attacks. The sputum culture showed aspergillus and was negative for tubercle bacilli. The x-ray showed massive cirrhosis of the hylus of the lung. He was put on large doses of potassium iodide and improved greatly, but the x-ray still showed masses of scar tissue. Two other cases had occurred in one family at the same time. The *Sporothrix shankii* was isolated, a parasite supposed to be derived from buckwheat. The infections had come on after the buckwheat crop. It was said among the population in the buckwheat raising country that those who worked among buckwheat plants were subject to chronic boils. This was clearly a mycosis infection. One woman showed lesions in which the pus had small black flecks, clearly a sporothrix.

Dr. W. W. FORD of Baltimore said he would like to confirm Dr. Emerson's observations in regard to buckwheat. In northern Ohio, a buckwheat district, boils were extremely common. This had been interpreted as increased sensitiveness to the buckwheat poison. The boils did not have the appearance of ordinary infections. No bacterial studies had been made so far as was known.

The Rat and Infantile Paralysis; a Theory.—Dr. M. W. RICHARDSON of Boston presented this, his second

communication on the subject. The possibility of transmission of human poliomyelitis by means of the rat and the flea was considered. That direct human transmission was not likely was shown by the fact that a block adjacent to an infected block was frequently untouched. Cases often occurred in the same house, but in different families. Nothing but the rat and the flea could effect such conditions. A comparative study with bubonic plague had been made. Great similarity was found in the phenomena. Rats were always noticed before the appearance of the plague, but it was not necessary to find the rats to prove the existence of the plague. The question "Does the rat suffer from paralysis?" had been answered. At the time of epidemics of infantile paralysis rats had been seen with paralyzed legs, and hardly able to move. Children who played with dead rats had been found to contract poliomyelitis within a short time. Since 1894 plague had become pandemic and had extended all over the world. Infantile paralysis had spread in about the same time. Rats were found to follow the grain traffic and a connection between infantile paralysis and grain traffic would have to be proved. In a very large number of rural epidemics the infections were found to start "at the mill." In plague the flea curve preceded the plague curve by about ten days, and it was found that it also occurred with the poliomyelitis curve. Water fronts, usually infested with rats, were commonly centers of infection. There was also a disease of rabbits which carried off large numbers every 6 or 7 years, and this was found coincident with the poliomyelitis years. Another point was that in plague the lesion was apt to occur where the patient was bitten, and in poliomyelitis the paralysis was most apt to occur in the lower limbs, which would be the ones to be bitten by the flea.

Major S. FLEXNER of New York said he was very much interested in the views of Dr. Richardson. The aspect of the epidemiology had received considerable attention, but the other aspects had also to be considered. The possibility of the reservoir of the virus was very evident to the men engaged in the study of the disease. It very soon came to light that there were cases of animal paralysis coincident with the outbreaks. Animals had been studied by the experimental method to see if any evidence could be secured to indicate epidemics in the lower animals. Paralytic disease of all kinds of animals had been studied. Material had been used for inoculation into monkeys, the only secure method for transmission of virus. The histological lesions in the man and the monkey were very characteristic. It was supposed that the effects would be similar. There was, however, no instance on record in which histological characteristics had been sufficient to compare the disease in animals with the disease in human beings, or in which inoculations could be successfully performed with the nervous tissues of animals on monkeys. Observers began early to use the reverse method. They tried domestic animals, mice, rats, rabbits, guinea-pigs, calves, sheep, goats, ponies, and cattle. They had never succeeded in producing characteristic poliomyelitis in those animals. Inoculations could cause death in rabbits but there was no histological change in the nervous system. In 1916 a large number of rats were collected from infected districts in Brooklyn, in order to test out Dr. Richardson's views. It seemed a promising direction in which to search for evidence. The nervous system of these animals was examined. Inoculations into the nervous systems of monkeys were made with the material from rats. In no instance was monkey poliomyelitis produced. The reverse method was then used. Active virus from monkeys was injected into rats to find out how long the virus survived in the nervous system. The tissue was then removed and put into monkeys to see if the virus survived. At the expiration of 7 days the virus had apparently disappeared. It would seem that if the virus did not survive this length of time in the rat, that the rat could not act as a reservoir. One could not say that Dr. Richardson's theory was disproven. The rat might be the reservoir and the flea, under favorable circumstances, might carry the disease to human beings. Dr. Richardson had brought together a very interesting series of observations and the meeting should be indebted to him for the knowledge of the subject which he had put into the question. It was,

however, necessary to go very slowly and cautiously. Workers now possessed what the earlier workers did not possess, when they demonstrated the transmission of malaria by the mosquito. The experimental evidence was necessary to corroborate epidemiologic evidence of the relation between the rat and poliomyelitis.

Dr. M. RICHARDSON asked Dr. Flexner if the rats were old or young which they had obtained from the infected districts in Brooklyn.

Dr. FLEXNER said they were fairly young, white rats.

Dr. RICHARDSON said the diseased rats might be done away with, and the old rats would not be likely to have the disease. If there was anything in the theory of rat transmission, it would appear in the trenches which were known to be overrun with rats. In one sector of the trenches 11 cases had been reported. This was an unusual number among adults.

(To be continued.)

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

FACTS AND FANCIES ABOUT TONSILS.*

By HENRY L. SWAIN, M.D.,

NEW HAVEN, CONN.

PROFESSOR OF OTOTOLOGY, YALE MEDICAL SCHOOL.

A PATIENT came to me the other day and said: "Is there any other way of knowing whether my tonsils ought to be taken out because they may be causing my wrist trouble, than to put me through the dreadful ordeal and expense of the operation of removal?"

It is this question with the facts and fancies involved in answering it that moves me to ask you to go over with me this evening one of the burning questions of the hour. Sins of omission, sins of commission are being laid at our door by a long suffering public which occasionally stops and thinks. Let us reason together. Though our sins be as scarlet yet shall they be white as snow—forgiven—if out of a nebulous conception of duty we shall by any such deliberation be led into any better light, any clearer, more exact knowledge of when, what, and how to do in matters of this kind.

To bring the matter properly before you, the previous history of the patient who asked these questions is intensely interesting. Told in her words:

I have been having so-called rheumatic symptoms of various kinds, and now for a long time they have been principally in the wrist. I have dieted, taken medicine, and I was told by a physician that my nose needed an operation before I could expect to feel better. He did some work and then wanted to do a big operation on my bone. This I delayed doing, because I could not see my way clear to do it at that time, and finally I visited a physician who, with great insistence, said that I could only be improved by having certain of my teeth out. He took some x-ray pictures and I have had many of my teeth extracted. I had a lot of trouble following the extraction and have never been able to get a set of teeth which are anywhere near comfortable. I cannot chew properly and nothing tastes right, and all this has told on my appetite and nerves. I was finally sent to another nose and throat man and asked whether I ought to have an operation done on my nose, and to inquire whether the tonsils could be causing the trouble. This man looked me over very carefully. He was of the opinion that my nose could by no chance be causing any absorption to give me my painful wrists. The tonsils did have some pockets which were retaining matter and might possibly be causing some trouble, although he very much doubted it. A good plan he had found in previous cases was to slit these pockets up and fix them so that they certainly would make much less trouble, allowing that they were causing any. He did all that he thought was necessary and, having had no change whatever in my wrists, he wondered if it could

be, as it sometimes is, some other portion of my throat. From the back of my palate I am always sucking down matter, especially mornings, and he thought treating that region for a while might lead to some further clue as to the source of infection. I did not quite want to do that, and as the man who treated my nose before had always done me a lot of good I thought I would look him up once more. He (forgetting all about my nose) immediately looked into my throat and squeezed what he called pus out of my tonsils, and said they were something dreadful and ought to come out immediately. Taking out his appointment book to make a date for the operation. When I told him that I recently had had a very distinguished man say that my tonsils were all cured up he was very much at a loss to understand the situation, but insisted on making the date, so I am going to try once more. He will take my tonsils out (mentioning a date), but what I would like to know is what a poor patient is going to do when opinions differ so, and if there is any other way to know whether the tonsils need to come out except to remove them. I have followed all the advice given and, after six months of endeavor and expense and no end of discomfort and trouble, I am no nearer being cured than before.*

A sad tale of woe, and a sadder commentary on "medicine as she is practised." The fact remains that notwithstanding all the exceedingly interesting and brilliant work that has been done in the last few years all of our boasted progress leaves us still adrift and still lacking a chart, compass, and chronometer to guide us accurately in our attempt to steer the wandering derelicts to a safe harbor of convalescence and perfect health. You all remember how only a few years ago all these complaints were supposed to be due to errors in diet and faulty assimilation. Men rose in this and every other center who not only professed, but were actually able to make many patients much better by a purin-free or otherwise altered diet. We listened as you are now so patiently doing to long harangues on the subject. These patients, however, did not lose decayed teeth or decadent tonsils, and yet some of these were benefited. Recently we have heard in this hall some most interesting cases where wonderful results came from removing tonsils and on another occasion teeth, and so now every sufferer and even the consulted physician wonders if he is doing his duty in letting any such escape without tonsillectomy and a full set of false teeth. In the minds of some of us the sequence should always be, first the teeth and then the tonsils. But regarding the latter it is certainly a frequent answer to the question to say the tonsils do not amount to anything anyway; who ever heard of anyone having bad results from being without his tonsils? So when we have reason to question what to do next,

*Since the paper was written the patient had her tonsils removed most skillfully and later the nasal operation first proposed was performed. At present there is only a very trifling amount of pain in one joint and the patient is much improved. What did it?

*Read before New Haven Medical Association, Feb. 8, 1918.

"Out with them." Nobody loves them and they do cause a lot of harm.

As years go by more and more obscure diseased conditions grossly classed under the name—which covers a multitude of sins—"focal infections" are being traced to one or another condition of the tonsils and the teeth. Wherever in a body a locus minoris resistentiae exists, thither the absorbed matter may be conducted and there make a rheumatism, a neuritis, a stiff joint, a painful muscle, a thyroiditis, a nephritis, a leucemia, or an endocarditis. Orchitis, as we have known for centuries I presume, is sometimes due to inflammation of the parotid gland so that the principle of the vicarious effects of inflammation has been easily accepted by the profession and laity alike. Some of these conditions produced are no worse than a feeling of malaise and general debility, so distressing, however, that one physician the other day related the remarkable comfort he had received, not only from the apparent cure of a so-called rheumatic tendency which so nearly cost his life that it was on one occasion despaired of for days, but also what was to him of most importance, his relief from the dragged and tired feeling which made him dread the next day's awakening, so much did he have to force himself. From such complaints as that, to having a disease of a fatal tendency is quite a jump, but any or all of the diseases mentioned except the cases of leucemia and endocarditis due to streptococemia of the viridans variety have either been cured or improved by the removal of tonsils when the latter were the cause of the trouble. But on the other hand, sometimes and often they are not. In some of these latter instances the tonsillectomized patient has an awful sore throat or has nearly bled to death, or has a distorted palate and a nasal voice because the endeavor was to do a very thorough operation, or, lastly, he was carelessly, on the part of his medical attendant, told that at least he would not have as many sore throats. His cup of complaint is full when he learns to his sorrow that not only is that not the case, but his sore throats are different and sometimes more painful even than before. Somebody comes along and finds a tooth needs attention or a discharging nasal accessory sinus or, as in an instance known to me, a very painful knee is later relieved by wearing sensible shoes and a lame shoulder has been relieved by asking the patient not to sleep with her arm under her head. We all strive for the remarkable, the striking. The humdrum cases tire and bore us and on the other hands our patients in this, the eminently surgical age, are impatient. They like a man who comes to them when they have a sore throat and says: "You do not need to have these painful times; you have a tonsillitis. Have your tonsils out and everything will be all right," ignoring the fact that all sore throats are not due to the tonsils, and therefore not to be cured by removing these latter. It must also not be assumed that it is a simple thing to have the tonsils removed as is done nowadays. The younger members of the profession know of nothing but tonsillectomy and there is much more blood lost in one of these and more avenues for new infections opened up in a non-sterile field than occurs in an interval appendix operation as is usually done by the modern surgeon. It may take weeks to recover, and life

has even been lost to prove this simple question as to whether the tonsils are the cause of the focal disease.

In spite of every care the luck of war will go against us and a little one slips away from us into the other world—no oftener than the usual operative risk, but one would like to feel sure of the necessity of taking these risks which I have not in the least exaggerated. In view of these, there ought to be some more exact method of deciding whether to operate or not, than merely to say inanely that we cannot find anything else to lay it to, so let us get the tonsils out.

So far we have only touched the high spots in the question of focal infection, and what about the group of children who every operating day in all of the large hospitals all over the country are brought one after another, anesthetized, into the operating room, and whatever they may have in the way of adenoids and tonsils are quickly removed from them. The dexterity of the operating surgeon becomes so automatic that it is to the lay onlooker a most marvelous and wonderful thing. A carping mind might sometimes wonder if some of the smaller bits of removed tissue really are a source of trouble or a great menace. Yet there are some men who think and write as quoted to you the other evening that the human race would all be better if we all of us had our tonsils and adenoids removed as a routine procedure before we are four years old. With such there can be no discussion. Usually, however, the little creatures are sent to us at the hospital because the tonsils and adenoids are large enough to be in the way and ought to be removed, or it is feared they will be, or there has been history of so frequent infections that it is best not to allow the suspected tissues to remain longer as a menace. (If, this tissue is ever a menace then it is always a menace to everyone, is apparently the usual method of reasoning.) In older people referred to the hospital, it is a question of enlarged glands in the neck, the probability of tuberculosis, and the plague of frequently repeated attacks of quinsy as well as the question of focal disease. The hope that by the complete removal in children the exanthemata and even infantile paralysis may be avoided, and susceptibility to colds and earaches banished, all inspire to make it seem that we could not possibly have any use for these lymphatic structures.

Of course, it might be reasoned that if the good Lord really wanted us not to have them he could have managed it so that we should not all of us been born with them. He might have let a few have them so as to keep the laryngologists busy and good natured, but a few of us might have been allowed to get by without them. Surely a much favored few. However, it may also be equally cogently urged that, inasmuch as the Lord did give all of us some of this kind of tissue, and as He also did allow animals to have tonsils, not reserving these blessings exclusively for the human race, there is in the great scheme of nature some reason why they are there. Animals and the untutored or uncivilized savage seem to have but little trouble from these directly. Civilized man has his full share almost in proportion to the degree of civilization. However, the fact is that in the developing embryo the pharynx tonsil or adenoid and the faucial ap-

pear early and always. No one has to my knowledge ever recorded a case of absence of the tonsils where everything else was all right. At birth there is plenty of lymphoid deposit at the base of the tongue. The adenoid or pharynx tonsil comes into prominence first, works out its mission in life when not cut short in its career by the ruthless surgeon of the time, and normally shrinks, practically disappearing analogously with the thymus gland. The faucial tonsils come in for their share of the work for good or ill about the time when the first molar teeth are erupted. They, the faucials, in their turn have a rise, a maximum, and a fall in their physiological activity, sometimes showing a marked decrease in size when a serious systemic drain, such as typhoid fever or chronic malaria, makes the system need more white cells. In late youth or early adult life the lingual tonsil takes up the work and carries it on well into the late forties or fifties if one chances to live that long. This seems to argue for intent and purpose in the divine scheme. Therefore the tonsils, one and all, are not merely residual organs. The first layers of lymphoid tissue forming in the embryo at the junction of epiblast and hypoblast are in certain places thickened up into large masses with much later a capsule forming and separating them from the surrounding structures. These masses are called tonsils. In other places the tissue is spread out more diffusely as on the posterior pharyngeal wall and lateral columns but in all places it is a distinctly lymphatic structure, part and parcel of the lymphatic system with which it directly communicates. The most highly developed or specialized portions are the faucial tonsils, the pharyngeal, and the lingual in order named. Here the resemblance to a lymph node is most noticeable. If this lymphoid tissue anywhere has any excuse for existence, then the most highly developed, refined, specialized portions must be the most useful and effective portions so long as healthy. Like most lymphoid tissue in the body, these portions are most active in the younger years of life, that is, during the growing period up to puberty.

It has been observed that if a part of this ring of lymphoid tissue is removed completely some other part takes up the work. If it is necessary to remove the adenoids very early, even without the known intervention of a single bad inflammation, the faucial tonsils will gradually enlarge. If, as I have numerous observations to confirm, the tonsils are removed before the period of physiological activity of the adenoid or third tonsil has passed, the adenoid will grow and have the same passive and functional hypertrophy of which we have spoken in the case of the faucial tonsils. The system needs it in some way and so functional activity develops it anew.

The lymph nodes in the neck also very frequently enlarge, do a given work, and recede. Sometimes in trying to "do their bit" they receive and hold up some tubercle bacilli and are removed then because being permanently enlarged, they are a menace. When healthy and behaving themselves, nobody ever heard of a recommendation that they be removed because they might make trouble later. And that is just what is done with the faucial tonsils largely perhaps because they are accessible and their removal leaves no external scar.

Through countless generation of existence through aeons of time in the development from unicellular to multicellular organisms, certain cells of the animal body have been differentiated for various purposes, and finally the highly specialized organs have been developed as in evidence in the human body of to-day. A humble but important office early developed upon the lymphatic structures and as such is handed down to the present time.

We recognize that certain of these tissues, if active, help to filter out and purify the fluids of the surrounding tissues which (actively or passively) pass through them. In this endeavor the lymph nodes seem to be the most active and capable and the tonsils, so-called, with their follicles and their phagocytes are certainly very properly to be ranked in this same category. If a tonsil is diseased it is a menace; if it is healthy it is not. Every faucial tonsil has crypts, every crypt in every human being has a fluid filling it, especially when it is deep set as in every large tonsil whether healthy or unhealthy. Large protruding tonsils often are much healthier than small buried ones. These tubular cavities filled with an organic fluid contained in a warm, moist chamber are always growing a numerous and diversified flora. There could not be conceived a better breeding ground; a better culture tube and incubator for germ growth never existed. Hence in every tonsil healthy or otherwise pure cultures of pathogenic germs may exist, but more frequently a symbiosis of numerous germs will be present. In the living human being there can never be for more than a moment or two a sterile tonsil crypt. The Peyer's patches of the intestine and the solitary follicles are other examples of similar lymphoid tissues, which, as they lead a more sequestered existence far from the usual haunts of the active foes of lymphoid tissue, pursue an unchallenged career. They exist in immediate contact with a cavity, the walls of which are bathed with all kinds of bacteria, many times of the putrefactive type. These lymph nodes sometimes, how often we do not know, are as in typhoid fever, well recognized pathologically. They absorb and they must occasionally succeed in purifying what they take in, or else ward off germs, because we do not all die. In fact, so far as known, very few of us pass out because of their failure. Still many a tubercle bacillus gets by and the mesenteric glands hold it up as a second or third line of trenches, and so the analogy with the faucial tonsil could be carried out quite to a finish. If we knew how we could support "Mr. Peyer, his patches," in their efforts in our behalf we would not, at least at present, want to remove them, for they are too numerous. Even if they hold up a tubercle bacillus we extol their efforts as desirable and praiseworthy, and yet allowing even the faintest reason for existence to similar tissue elsewhere, how we raise our hands in holy horror if anyone ever finds a tubercle bacillus in a section of tonsil tissue. Did you ever stop and think that such a tonsil was doing in this way just as yeomen a bit as every trench full of Yankees will do for a better civilization and for liberty, when it holds the foe up and keeps him until conquered. Remember it is only when they, the phagocytes in the tonsils, fail in their work that the germ gets into the second line trench, the lymph nodes of the neck. Many times therefore they kill the

tuberculous germs off, and it is lucky for us that they do. But suppose that, in consequence of previous disease or surgical intervention, neither the tonsils nor the lymph nodes are present, what happens when a lustier bacillus than usual manages to get in beyond the outer epithelium, free to make an insidious march where the current of lymph takes him?

I have often wondered if it was not safer to have a good healthy tonsil absorb the germs where there is tissue rich in phagocytes, as in the follicles, than some other region further up—equally permeable to a vigorous germ. It must at least be admitted for the sake of argument that some of us have gotten to a reasonable old age in possession of our tonsils and some of our teeth. Nobody will say that no exposure to disease has ever existed. Notwithstanding that our tonsil crypts have bred countless millions of germs we have lived along. Why? Because cells of active functioning powers have expelled the invaders. They have been hurled back into the mouth again and lost in the maelstrom of the secretion or carried into the stomach. Actual microscopic specimens are in existence showing crypts of the tonsils full of streptococci, but not one of them even in the interstices of the epithelium of the crypt; just as there are also specimens from perhaps the same tonsil showing the germs within the tissues, the attack having at that particular spot overwhelmed the sturdy defenders. Lack of reinforcements for the men (leucocytes), diminished resisting power because of weakness from long strain and most exhausting activity result in the fact that the battle is often to the strong. Some tonsils protect, some put up a very minimum resistance, some lie inanely down, while some actually seem to harbor disease, sedition, and rebellion and aid and abet the enemy.

How shall we separate the sheep from the goats? We cannot do so by removing every tonsil in every child. We certainly cannot thereby hope to breed a tonsilless race. Many live, revered, and respected, yes loved in spite of their tonsils. Removal of tonsils cannot always stop all sore throats or other absorptions, but, on the other hand, no more spectacular cures have occurred anywhere in the realm of medicine than have followed the removal of the tonsils. Hundreds of tonsils are removed, however, to one of these same brilliant results. Some operators excel others, do their work better. Allowing that we knew and could always tell which tonsil was making trouble and which not, then would we be able to escape the opprobrium which cannot fail to be cast upon our work, as evidenced in the care reported above.

Some of you have known of the desire on my part to find out some way to improve and be able to give a better opinion occasionally than to remove as the only way to determine. Seven years ago I wrote a paper "Are the Tonsils a Menace or a Protection?" I started out to write that paper, fully believing that one should not only not curtail, but should spur on to even greater activity. I came to conclusions which were expressed and summed up as follows:

First, that logically tonsil tissue must have a function, and if so it is to the young that it is of most value.

Second, if it is necessary to operate in children

upon the faucial tonsils, which are merely large and not diseased, then there surely are safe, sane, and effective methods other than complete tonsillectomy to deal with the problem. Be thorough with the adenoids, but save some healthy tonsil tissue.

Third, while what has just preceded may apply perfectly well to adults, in them the evidence of disease may be so apparent that radical procedures against the tonsil are surely justifiable; and then by all means do a tonsillectomy in any one of the admirable ways which you gentlemen have been so prominently identified in developing to a perfect detail.

Twenty-seven years ago I said some of the same things dealing with the academic question of the fate of the lymphoid tissue of the nasopharynx. This paper I had entirely forgotten when I wrote seven years ago, "whichever of these theories we adopt, we cannot escape from certain difficulties in trying to explain certain observed phenomena. For example, if the sole purpose of the adenoid tissue of the throat is to furnish leucocytes, which shall protect us from the invading host of rapacious microorganisms, then we may safely conclude that for those who breathe through the nose the pharynx tonsil is really the most valuable in this particular. Is it not strange, then, that this should be the first to atrophy, when it is the one most needed? To be sure there are other parts still left, but they cannot get at the inspired air. Or must we suppose that the pharynx tonsil takes care of the air, while the faucial and lingual do duty in fighting the organisms present in the secretions of the mouth and pharynx? This takes place in the youth of the individual, and later in the adult there is not such an urgent necessity for such protection, in that other organs may do the work or the system be more capable of resisting. Certainly if the above be the case we must not be hasty in removing enlargements of these organs unless we find them to be producing disease of other parts, for one cannot have too many leucocytes at his command. And yet while we find these little inconsistencies, surely we must almost *a priori* conclude that the leucocytes must exercise some protective influence, and that an active one, for how could we otherwise so often escape infection? Surely nothing would seem more favorable to the ingress of organisms in the system than the tonsils, which present in the lacunæ the most convenient of resting places for microbes, and then in the openings which unquestionably exist in the epithelium we have an almost open door for the entrance of the little micrococcus. Granted that the majority of the organisms referred to are entirely innocuous, still some are not, and were it not for some active interference we must often become infected under the conditions just quoted. So I think in the light of present knowledge we must give Killian's view a decided credence; but in view of the fact that the immensely larger number of the leucocytes present in the tissue do not ever get to the surface, and remembering the observations of Stohr, which I can in part second, as regards the diminution in the number of cells in adenoid tissue under strong demand for white blood corpuscles by the rest of the system, we must look upon the tissue as strictly lymphatic tissue—a blood-producing organ. And in the light of this view we can more easily explain the atrophy. Therefore the

function is twofold. As regards the theory of soaking up the fluid in the throat, it seems to me to be quite a secondary object, if it exists at all."

Writing at that time when ether operations for adenoids had just begun to be counseled and when the tonsils were never interfered with unless obstructive, dangers to life and the integrity of the parts were few and far between. Very young children for the most part escaped; and yet even at that time men differed in opinion regarding the tonsils, and this came eminently to the fore at the International Medical Congress in Copenhagen in 1884. Here the American delegates, notably Dr. Daly of Pittsburgh, created quite a furious discussion because of the assertion that all tonsils were pathological and should be removed whenever causing the slightest annoyance. But at that time operators never, except by chance, removed a tonsil, only chopping off the redundant tissues in the older operation called tonsillotomy. Nevertheless it is interesting to note that ideas move in circles, that there is nothing new under the sun, even the notion of getting rid of all lymphoid tissue wherever found. As time went on it became apparent that more must be done to the tonsils than merely to chop off redundancy, and so for the smaller tonsils various operations were devised, ignipuncture, slitting of the crypts, and removal of larger and smaller masses by the punch, the hot and cold snare, and still others. Finally there was developed the operation of the present time of tonsillectomy.

Here was a chance by one method to operate on both large and small tonsils alike. Even the wee small chaps buried out of sight might be dissected free by clever "smiths" and removed from chance of further harm. Then came the universal application of the method. It appealed to all as thorough, and with one of the most tremendous waves of approval ever given a special operation, unless perhaps that for straightening of the septum, a perfect furor for operating came into existence and still holds the stage with undiminished enthusiasm. Caught in the midst of this maddening swirl, the writer sought to get evidence to support him in his own efforts, but ended in writing the paper under the title given "Protection or Menace." Since then many papers have come out, stating that others have been led to similar feelings, and I will quote a few, if I may, as evidence. You all doubtless remember the wonderfully well expressed paper by the talented Dr. John N. Mackenzie⁸ of Baltimore, who spoke to the sentiment, "The Massacre of the Tonsil." He was one of the first to take up the cudgels for a wiser conservatism in the matter of operating. It is impossible to do this paper justice here, but this very title backed by the distinguished opinion of the writer made a tremendous impression. Following this a most interesting series of papers was brought out by the late G. Hudson Makuen, Professor of Defects of Speech,⁹ who demonstrated that resulting from ill-considered efforts many serious impairments of the voice occurred in consequence of injuries to the soft palate and its pillars. Some most grotesque throats will bear witness of the zeal if not the skill of the operators. Then Dr. French¹⁰ of Brooklyn did a most wonderful amount of work to perfect a method to decide in some more objective, definite way whether a tonsil should be re-

moved or not. Of this splendid endeavor and its results I will speak more at length later. Dr. Chas. W. Richardson¹¹ spoke lately to the sentiment, "Tonsillectomy in the adult; are we justified in doing so many indiscriminate tonsillectomies for remote infections." After detailing a number of cases where he had yielded to pressure, and had done the operation against his own judgment, and scored failures, he concluded his paper as follows: "It is hardly necessary to state that the operation for enucleation of the tonsils is a major operation of some gravity, having immediate and remote possibilities of danger to the welfare and life of the patient, and therefore should not be entered into without well defined and justifiable cause for their removal. I cannot but contemplate the removal of the tonsils which are apparently healthy, for the reason that they may prevent systemic infection, or because they may be the probable source of general infection, without a certain amount of misgiving. It seems to me, therefore, that one should most conscientiously consider every case wherein enucleation is suggested for chronic systemic infection, if the tonsils are not enlarged or show evidence of local pathological changes, and weigh carefully the clinical evidences, the possible existence of other infective foci, and the experience of the operator in previous cases of a similar character, as to the results obtained, before committing oneself to the suggestion of operative intervention."

Dr. Otto T. Freer¹² of Chicago said in part, in discussing Dr. Richardson's interesting and illuminating discourse: "A doctrine has of late years been ardently advocated by a group of Chicago men who may be called the focal infectionists, this doctrine attributing many chronic diseases, especially chronic arthritis, to chronic systemic infection originating in some latent or inconspicuous septic focus somewhere in the body, but nearly always in the tonsils. The doctrine has failed to convince the experienced because of the exaggerated claims made for it, which are contradicted by common experience. The majority, however, which unquestioningly follows authority, has been misled by this teaching into the indiscriminate removal of harmless tonsils because the statements of the focal infectionists make any tonsil, no matter how normal in appearance, or devoid of local symptoms of disease, a probable source of one of the multitude of diverse chronic ailments classified by them. That is, such an ailment is taken as unquestionable proof of causal tonsillar disease, whether such disease be locally evident or not, a dictum which is not supported by proof except of the questionable post hoc ergo propter hoc kind taken from case records, helped out by bacteriologic experiments, the more important gross and cellular pathology of the subject being ignored. The many tonsillectomies into which the medical public has thus been led have often been badly done by inexperienced operators, objectionable mutilations of the palate, septic conditions causing grave complications, and even death often resulting. In addition the numerous failures to remove by tonsillectomy the chronic ailment aimed at, are subjecting the profession to the criticism of groping and experimental therapy."

That general infections, notably acute articular rheumatism, may originate from infected tonsils,

is old and undisputed knowledge. This old knowledge, based on fact and long experience, has by exaggerated enthusiasm, been expanded into a theory of the most elastic kind, which claims to cure by tonsillectomy, chronic arthritis, chronic nephritis, goiter, and many other things with the assurance of a patent medicine advertisement.

In contrast to the presumptive tonsillar focus of infection whose existence is supposed to be disclosed by a pain in the back or a stiff neck, how does a real focus of infection as known to common surgical experience show itself? Most plainly in addition to evident local inflammatory symptoms by the infections of the nearest lymphatic glands. Thus a chronic root abscess will lead to tenderness of lymphatic glands, underneath the lower jaw; an abscess, ulcer, or bone disease of the lower extremity to swelling of the glands in the groin; a chronically inflamed tonsil with septic pockets similarly will lead to the well known enlargement of the cervical lymphatic glands. The road travelled by such infections from the tonsils is especially often seen in childhood, where greatly enlarged and even suppurating glands in the neck accompany tonsillar disease, but in children, in whom because of the great prevalence of septic conditions in the tonsils, the chronic disease of the focalists should be especially prevalent, they are exceedingly rare. They are also rare in connection with many chronically inflamed and infected tonsils removed because of local tonsillar symptoms by nose and throat surgeons, although, if the focalists' theory be true, such tonsils should be the very ones most often complicated by the systemic chronic diseases, supposed to be of tonsillar origin; for, if the latent tonsillar focus of the focalist can cause them, although too insignificant to affect even the nearest lymphatic glands, tonsils containing foci formidable enough to enlarge these glands and demand tonsillectomy because of the throat distress they occasion, should not only lead to these chronic affections invariably, but also in a far more marked degree than the hypothetical little focus of the focalist.

In respect to remains of the pharyngeal tonsil my observation agrees with Dr. Logan's that a large number of cases of acute and chronic tonsillar infection are merely secondary to diseased states of the pharyngeal tonsils or its remains, and I think that the faucial tonsils have received the undue attention accorded to them chiefly because they are so accessible and visible, and that the pharyngeal tonsil, though even more liable to acute and chronic infection, escapes notice because of its hidden seat. Dr. Richardson has done conservative rational tonsil surgery a great service in presenting his admirable article.

This year in Chicago they had a discussion at their local laryngological association around the papers of Dr. Boot⁸ and Dr. Shambaugh,⁹ the former speaking to the question in children and the latter to that in adults. To quote from Dr. Boot's very sane paper: "There is no doubt of the fact that the tonsils are more active in childhood than in later life. If a tonsil is normal up to the age of puberty it becomes so largely fibrous that in adult life it is of little or no importance functionally. The younger the child the more active the tonsil, and the more

we should hesitate about advising tonsillectomy. The ease with which the tonsils enlarge during any infection of the throat in children shows them to be very active. The fact that many of these enlargements will subside with proper attention seems to be largely overlooked by the general practitioner, and at times even by men devoting themselves to children's diseases. If a child with acutely enlarged tonsils is put on syrup ferri iodidi for two or three weeks, a wonderful reduction in size often follows, and many children with enlarged tonsils but with no cheesy plugs or pus in the crypts should be treated before deciding that tonsillectomy is needed. We are often asked to remove tonsils in children because of habitual colds. Unless the tonsils are so large that they obstruct the nasopharynx, or unless there are other reasons for their removal, I discourage tonsillectomy in such cases. It has not been my experience that removal of tonsils influences head colds, unless they are large or plainly infected. Removal of adenoids in such cases is another problem.

"There are many islets of lymphoid tissue scattered over the pharynx, and especially behind the posterior pillars. These islets seem to be particularly prone to compensatory enlargement if the tonsils are removed in early childhood. The condition that results is much like chronic granular pharyngitis from any other cause. This is one of the disadvantages that should be kept in mind in recommending tonsillectomy in children. Hypertrophy, the classic indication for tonsillectomy, may or may not require the operation. If the tonsils are so large that they obstruct the nasopharynx, remove them. If they are the projecting kind that on cursory examination seem large simply because they are all seen and no part is hidden behind the anterior pillar or in the velum, then it matters little whether they are removed or not. These are the easiest removed, with the least resulting deformity and ordinarily with no particular change in the child's condition. Such a tonsil is rarely the seat of a focal infection or the cause of a tubal occlusion. It can be removed by any method with perfect satisfaction, and is the kind that leads the occasional operator to think he is capable of doing tonsillectomy.

"Operate only for definite disease. Be sure the condition of the tonsil is the cause of the disease. Don't destroy a functioning organ unless the gain more than offsets the loss. The younger the patient, the more carefully the need of tonsillectomy should be established."

Dr. Shambaugh summed up quite clearly as follows: "It is evident, therefore, that there may be cases where neither from the history of acute attacks of tonsillitis or from the local findings in the tonsils is there any positive evidence of tonsil infection, and still they may be the seat of an infection capable of producing the most serious systemic trouble. It is this class of cases where the indication for removal of the tonsil is the most difficult to work out. Because such cases are known to occur must not be construed as an indication for indiscriminate tonsillectomies in cases suffering from systemic infection. Only in cases where the systemic infection is of a serious character, and where a careful search by a competent internist has failed to discover any probable focus of infection, should

the advice be given to have the tonsils removed. The operation for the removal of tonsils in adults is by no means a minor operation, and while the indications for this operation have been greatly increased by a better appreciation of the menace existing in tonsils when the seat of chronic infections, still it is quite evident that the indiscriminate removal of tonsils in adults is to be discouraged. The decision to remove the tonsil can be reached in a great many cases only after a careful investigation, which, to be complete, requires the cooperation of the internist."

In discussion of these papers Dr. Norval H. Pierce¹ said it seemed to him that there was very little left to discuss. He heartily agreed with most of the things said in the two papers. He was happy to see that they condemned the massacre of the tonsils which had been going on. He thought that there was no doubt that there had been an enormous amount of unnecessary operations, especially in children. An adult can protect himself, but a child is the victim of his physician or overanxious parents. This is seen constantly at the dispensary of the Illinois Eye and Ear Infirmary and St. Luke's Hospital. He was sure he was right in saying that in the cases which he inspected immediately before operation, which had been prepared for operation, fully 15 to 20 per cent. were turned away and not operated upon. The visiting nurse and the physicians in charge of schools have been obsessed by the desire to remove all tonsillar tissue in the human race.

He considers the indications for tonsillectomies in the child to be about the same as those in the adult, with perhaps the exception apparently in the minds of those in charge of children, that all tonsils should be removed if they were at all enlarged. He agreed with Dr. Boot that the mere enlargement of a tonsil did not indicate operation. A tonsil can be quite large, but if it is not embedded and not the seat of recurrent attacks of inflammation, it should remain in the child.

As Dr. Boot had said, such tonsils very frequently undergo reduction in size very rapidly under syrup of iodide of iron or potassium. It is true that very little harm comes to a child from the removal of tonsils, other than the dangers necessarily dependent on the operation. It is remarkable how small a mortality there is in tonsillar operations, but he is quite sure that we do not accurately know the mortality. We accidentally hear about septic pneumonia, infarcts, hemorrhages, and sepsis, but very rarely read about them in the literature. He is quite sure that removing the tonsils in children must be a more or less dangerous operation—we know it is so in adults—and he believes we should be very circumspect in recommending any operation on the tonsil.

He thought Dr. Shambaugh had handled the question as to indications suffering from focal infections in a masterly manner. The crux in the matter in these adults, he thought, was represented in such a case as this: An internist sends a patient to a laryngologist for removal of the tonsils. He tells the specialist that he has very carefully gone over the patient with Bright's disease, or neuritis, or a rheumatic type of disease, and has found absolutely nothing; therefore, the tonsils must bear the brunt

of suspicion. He recommends the removal of the tonsils. There is no manifestation of local disease, there is no history of sore throat, or only a slight one now and then; nothing can be squeezed out of the tonsils—no cheesy matter or pus. They may or may not be imbedded. Should we yield to the internist, and remove these tonsils? He admitted that he had been guilty of yielding in this way, but he has yet to see in such cases any benefit whatever from such an operation. It is probably true, although personally he had never seen such a case, that tonsils had been removed in cases with focal infection symptoms in which the tonsils, before operation, exhibited no sign of inflammation, yet the operator has found at the base of the tonsil, absolutely sequestered, a small abscess. He has seen cheesy matter deep in the tonsil that could not be expressed by pressure, but he has never seen a real abscess deep in the tonsil without manifestation of it in the tonsil before operation. He has yet to see a good singer hurt in any way by a tonsillectomy well performed. He has seen young women who said that their singing voices were entirely lost from removal of the tonsils, but he was in a position to know that they had never had a voice and never would have a voice. They were willing singers, but not gifted singers.

Dr. Elmer L. Kenyon said that since the question of voice had been brought up, perhaps it was just as well to make a remark about it. Last winter he examined some forty or fifty tonsillectomized throats, with the purpose of determining exactly what had happened to the palatoglossus and palatopharyngeus muscles. In that series of cases five voices were found to have become permanently nasalized. That is a terrible percentage. If that ratio held in all operations it would mean that one out of five had permanently nasalized voices; but, of course, that is impossible. These findings did not represent at all the true percentage, but they almost certainly did show that there was more injury to the speaking voice following tonsillectomy than any of us had thought. In all of these cases the trouble with the voice had resulted from a permanent injury to the palatopharyngeus muscle. That muscle had been pulled to one side and become adherent to the outer wall, with the effect that the soft palate was held down, making it impossible for it to move back to the posterior pharyngeal wall on phonation.

At this meeting Dr. Beck² of Chicago was also present, and, as a result, wrote a paper about "The Tonsil in Children and Adults," rather than trust himself to speak in extenso from the floor. In this paper he discusses the subject in the sense of the "get the tonsil habit," following the line of least resistance in that so long as the tonsils have no known function, and as no one was ever any worse for being without them, inasmuch as many are much better minus these impedimenta, remove them always when in doubt. Better remove in focal disease, because by failure to remove you might miss a chance to do good. His paper is replete with suggestions as to methods and instruments, and written by a man of his talent makes a deep impression for radicalism. In discussing it, Dr. Pierce of Chicago again gives us food for thought. He said in part: "Still his paper did bring out points for discussion. The axiom which he voiced at the

beginning of his paper, 'that a tonsil is better out than in,' Dr. Pierce disagreed with. If we accepted such a position it would eliminate all intelligent consideration of the subject. It would be very easy, if a patient came to you with a pair of tonsils, without any further consideration to say 'your tonsils must be removed.' That mode of action has brought numerous procedures into disrepute. It is a position which surgical men have condemned in all branches, and it is the very turning point between humanely directed effort in medical practice and the veriest quack who has nothing in view but his fees. There is something besides merely removing the tonsils; there is the danger that the patient is exposed to—a danger which has not been properly appreciated, the danger from the anesthetic and of shock, whether of local or general; the danger of sepsis, the danger of pneumonia, etc., and every patient who is subjected to tonsillectomy is liable to all of these dangers. But aside from that, Dr. Pierce still claimed that the tonsil must perform some function in the human economy. This is shown by the fact Dr. Beck brought out, that even after a year a very careful, complete tonsillectomy there will be most pronounced hyperplasia. Nature is trying to do something to take the place of the excised tonsillar tissue.

Dr. George W. Boot believed that most of what Dr. Pierce and Dr. Beck had said was right, but he must disagree with part of Dr. Beck's statements. He had recently attended a meeting where one of the doctors urged that the people get the "tonsil habit." He thought it a bad habit for the people to get. It is bad enough for the doctors to get the habit. One of the first things impressed upon him as a student of medicine was to do his patient no harm, even though he did him no good. He thought no one could deny that in removing tonsils the patient was subjected to some danger. Occasionally lung abscesses have followed tonsillectomy, and there are all manner of other bad effects that are seen, such as absence of the uvula, soft palate, artificial cleft palate, and so on; so that we can hardly deny the danger of the operation, and we have no right to subject our patients to such danger without justification. These results are not always from the work of beginners, but some of them have followed the work of very good men, and he thought one should be careful in urging the laity to get the 'tonsil habit.' "

In an article on "Pernicious Anemia," by Barker and Sprunt,¹³ the following comments were made concerning the removal of tonsils and other things. In the mouth, stomatitis and glossitis receive appropriate local applications; infected teeth are extracted, and the sockets are curetted and treated for a few days with iodine solution; gingivitis and pyorrhea alveolaris are treated by a pyorrhea specialist. Any teeth loosened by pyorrhea are extracted. Pyorrheal pockets are carefully curetted and locally treated. After the mouth has been put in good condition the patient is instructed in the details of a proper mouth toilet, the nurse seeing to it that the technique is acquired and regularly applied.

In the nose, throat, and ear, any active infection found is treated at once. For example, a suppurating sinus (antrum, ethmoid, etc.) will be drained;

infected adenoids or badly infected tonsils will be removed, though great care should be taken not to subject the patient to an operation on the tonsils merely because they are adherent or because tonsillitis has previously existed. Here the common sense of the physician in charge may often be required to check the cacoethes secandi of an overzealous specialist. Similarly the best judgment of the physician will be called on in deciding for or against operation for suspected infection elsewhere (gall-bladder, appendix, renal pelvis, endometrium, etc.). In our experience infections of the teeth and gums have more often than any other infections required immediate attention in pernicious anemia. Rapid improvement has so frequently followed the treatment of such oral sepsis that we cannot help but feel, with William Hunter, that this side of the treatment is, in many cases, very important, and that poisoning from oral sepsis may, in some cases at least, play an etiological role.

Granting every concession to men who may differ in opinion with me as the result of their operative experience, there is nevertheless to my mind no doubt that far too many tonsillectomies have been done in the past. It is certainly utterly unscientific and begging the question to shrug one's shoulders and say, "The tonsils don't amount to anything anyway; what's the use of talking about it." Equally illogical, reactionary, and puerile, would it be to belittle in any way, or by ignoring the work of others, deprive any of our patients from receiving the good results to be obtained by properly studying the teeth or which have come from such splendid work, as has been done all over the world in perfecting the operation of tonsillectomy, and notably by two men we have with us tonight, Dr. Smith of Hartford and your president, Dr. Sperry. Each has perfected a method of operating in which no one can excel and even few approach them. What should be done is in all sincerity to try and improve as so nobly shown us by Dr. French in our knowledge of the problem of how to be accurate enough in our diagnosis and estimate not to put our patients through unnecessary operations. This would be the only reasonable thing to do from the standpoint of simple everyday justice to our patients. We should face the proposition fairly, squarely, and conscientiously.

Let us for a moment assume what seems to me is proven, that our tonsils exist for good and sufficient reasons, and that when normal they are a part of us which should remain unmolested. How are we to know when they are not normal? This question Dr. French of Brooklyn has tried to answer. He first devised a method whereby he could examine a piece from every tonsil excised after the anesthesia was begun. This was in brief an old-fashioned incomplete tonsillotomy which was plenty good enough for a great many years and in hundreds of thousands of cases. This tissue was immediately examined by a transilluminating light under very strong magnification. If unhealthy the rest of the tonsil was removed in its entirety by the Sluder method. If found healthy, more or less was allowed to remain. This method was a little slow and cumbersome and he devised his present improved method whereby a light is passed behind the tonsil *in situ* and before the operation is be-

gun at all. By this means the sheep are separated from the goats and the wicked tonsils removed. This method under proper cocaineization can be used in adults. The answer to the question, what is healthy or unhealthy tonsil tissue, Dr. French has settled for us by the very beautiful paintings of the tonsils so illuminated. To aid one in becoming experienced in deciding about these tissues, he devised a little dark box into which the excised tonsils could be put and there studied, the observer thus acquiring facility in judgment. Dr. French summed up his discoveries in such a way that I wish I might quote him at length. As this is a terribly long drawn out affair already I forbear and will briefly state the most interesting results of this painstaking piece of work occupying three years, one of the most edifying examples I have ever seen of what pluck and determination can accomplish by hard work, especially if one has the cooperation of his comrades in his work. His classification you have before you. He learned that "one and two" may be allowed to remain. The rest ought to be treated—or removed. So cheer up all you ardent operators—for over four-fifths of all enlarged tonsils are in the last four classes after the age of six or eight up to adult years, when all are included.

Secondly, a large number of tonsils needing operation can in adults and older children be cured, and most brilliant results obtained by simply opening the foci of disease and curetting, without necessarily passing through the ordeal of tonsillectomy. I know the above to be truer even than stated here by an abundant experience through many years.

Thirdly, one can often learn that the tonsils are very hyperemic, and being forewarned is forearmed for any increasing danger from hemorrhage.

Fourthly, when one is a wee bit stumped where to locate a focus of pus in a quinsy, the small transilluminating lamp placed behind the tonsil will be very revealing.

This is but a very parsimonious excerpt from the wealth of observation chronicled in his paper. You must read it to appreciate what I mean. Having for years developed and practised the more conservative methods of dealing with diseased tonsils you can well imagine the pleasure which I have experienced from Dr. French's assertion that he has had some of the most brilliant results from measures even more conservative than my own. In addition, a recent article by Dr. Murphy¹ on the trouble caused by the redundancy of the plica triangularis overlapping the tonsil is most interesting. The simple removal of the plica makes many a patient free from all his tonsil trouble.

The conservative remarks by the various men quoted, together with the opinion of many others, bring me to believe in all sincerity:

First, inasmuch as many tonsils require removal, when this is necessary there is no way as good nor anywhere nearly as satisfactory from every standpoint as tonsillectomy. When possible I use the Sluder-Beck method as developed by Dr. Sperry. He can get many more by that method than can I. Where that method will not suffice I work by a combination dissection and snare method, a very poor imitation of what Dr. Smith does so very well.

Secondly, by preference, whenever I can, I prove the necessity for graver procedures by first trying

the more conservative. By this latter I often succeed, and I think it only fair to infirm, or delicate, or timid folks, to do the easiest way for them. They have a right not to be dragged through the more serious ordeal when unnecessary.

Thirdly, in children, especially under six or eight, one should be just as thorough as is possible—if necessary reoperating, in order to get rid of all adenoid or third tonsil. Unless very large or the cause of much trouble, the faucials are allowed to remain. When the child is under the anesthetic, some operators always remove the tonsils when operating for adenoids. By simply seeing that the plica is freed from the tonsil, and the tonsil from adhesion to the pillar, small unsuspected tonsils can certainly quite safely be allowed to remain and do some good to the growing child.

Fourthly, every tonsil worthy of the name will at some time have thick white cheesy matter in its crypts, large ones almost always. This will almost always squeeze out when the tonsil is snared out in operation, quite generally it appears when a tonsil is squeezed by a spud or by the edge of a tongue depressor. To accept this as the criterion for operation, means that you must remove every tonsil, for as we have just said this probably happens at some time to every tonsil. Simply slitting up a crypt or two or punching out the partitions between them will remove this tendency to accumulate and, therefore, one indication for tonsillectomy. If accumulation continues, remove, but to say that because once or twice a year a simple sore throat occurs, or a bit of accumulation is found that often, is not to my mind a logical indication for removal in toto.

Fifthly, it would seem only fair to think that we all (and this whole paper is written in no "holier than thou" spirit for any error here defined has been also laid at my own door) ought to remember and explain to our patients—and this applies alike to internist, surgeon, and specialist—that too much must not be promised or expected as a result of the tonsillar operation, for otherwise we greatly mar the splendid work done in our own circle and elsewhere, to perfect the operation of tonsillectomy, doing thereby a great injustice.

Finally, would it not be a most beneficent action if by any chance some of this effort which the world over has been spent on the mere mechanical aspects of removal of the tonsil, could be diverted to studying the broader question, whence come the germs which get into noses and throats and make all this trouble. They come from some given source, to be sure perpetuated by carriers of the human variety, but is it too Utopian to expect that some of the tireless workers in the laboratories may discover just this source of trouble, and as was the case with malarial parasites, also a means to prevent their growth and spread. May God speed that day.

195 CHURCH STREET.

SELECT MEDICATION IN CHILDREN.*

BY HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

IN the practice of medicine, in contradistinction to surgery, every physician, I believe, passes through three well-defined psychologic experiences in the first few years of his momentous career. Overwhelmed by the enthusiasm over the infallibility of drugs as impressed upon him during his college days by the learned professor of *materia medica*, he enters into the medical arena with boundless confidence in his power to cope with every phase of disease and anxiously awaits the opportunity to demonstrate and to reap the benefit of his skill. In the early period of his career he may luckily find encouragement for his belief and anticipations, rarely, if at all, surmising that many of the cures he happened to effect were in reality only natural or accidental events, often based upon false premises, erroneous diagnoses. Lo and behold! A few unexpected failures and his fantastic dream is cruelly shattered.

With multiplying failures the state of exultation is gradually replaced by that of depression, his hyperoptimism changes into hyperpessimism. His growing skepticism in the efficiency of medicines often leads him to seek unalloyed selfsufficiency in one of the many fields of surgery. Or, if he is over susceptible to the pricking of his conscience, he even goes as far as to abandon his profession entirely, little realizing that no profession, trade, or business has attained the millenium of righteousness and immaculate dealing with his fellowmen. Some physicians, though continuing to practice medicine, permanently float in the "river of doubt," prescribe nostrums and placebos or fall in the trap of the polished patent medicine mercenary or promoter of some newly discovered, but invariably threadbare, mechanical device or manipulation, or spiritual panacea, cult or science.

Fortunately most of us are not so readily swayed from the straight path of duty by such melancholy philosophy. On the contrary, we continue conscientiously to minister to the sick and to strive to perfect our knowledge in accord with the scientific advances of modern medicine. Indeed, as with many years of hard work and careful study our

*Read before the Bronx Medical Association, April, 1918.

powers of intuition and judgment improve and we acquire a higher degree of skill to select the most appropriate remedial measures to combat disease, we soon find ourselves in the happy psychic state of equanimity and self-reliance and contentment with our noble mission, undaunted by occasional failures and untainted by triumph, fully conscious of the limitations of medicine, yet perfectly confident in our ability to relieve suffering, prevent disease, and prolong life.

Having safely survived the trials and tribulations, the vicissitudes and temptations that becloud the horizon of the young practitioner, I take the liberty of appearing before you with a few suggestions regarding the selection of the most efficient medicinal preparations which may aid you to surmount some of the aforementioned difficulties.

Those of us who believe in the therapeutic value of the drugs they prescribe must, first of all, see to it, that their patients are able to swallow and retain them. As a rule, adults manage by means of capsules or condiments to render medicines disgusting in taste either tasteless or at least acceptable. On the other hand, children are compelled to take the medicine as given to them, and what is still worse, the more they resist, the more they are subjected to anguish and distress, nay, even to severe corporal punishment, which not rarely borders on serious injury.

Indeed, it is not at all rare to find little children, suffering from acute lung or heart disease, in a state nigh to suffocation from the effects of prolonged and firm compression of the nostrils, and many a helpless child bleeds from the lips and gums and even loses a tooth or two in the struggle with the overzealous mother who is determined to force down its throat a teaspoonful of a miserable decoction, which was, perhaps, intended only as a placebo. There is certainly no excuse for such cruelty, much less so in the present state of pharmaceutical progress, which, as I am about to attempt to show, enables us to select and administer the most potent drugs in concentrated and palatable form.

For the sake of convenience and in order to avoid unnecessary repetition I shall endeavor to follow the usual classification of drugs in accord with their therapeutic action.

Digestants.—Except in combination with other drugs digestants are rarely needed in the treatment of diseases of children. Occasionally pancreatin is indicated in starch-indigestion of infants, and may be prescribed either in powder form with bicarbonate of soda or the diastatic essence with or without a small quantity of milk of magnesia. The latter combination mixed with glycerin and fennel-seed water may be found useful in colic. Altogether digestants occupy but an infinitesimal space in pediatric practice.

Tonics.—The simple bitters fully deserve their striking cognomen, since they are surely very bitter and simple, insignificant, in therapeutic action. I believe that the tinctures of gentian, quassia, calumba, and even cinchona owe their trifling medicinal quality to the alcohol they contain. Their use in children, therefore, is hardly to be commended. Whenever a bitter tonic is desired, we

should preferably resort to a minute dose of *nux vomica*.

Of the so-called Aromatic Bitters *eucalyptol* is the only preparation worth mentioning. Internally it may be administered in one- or two-drop doses, thoroughly mixed with honey, glycerin, and mucilage, in cases of spasmodic asthma or laryngitis, and in the same affections it is very useful as an inhalation, especially if combined with the compound tincture of benzoin.

Quinine, which is erroneously classed among the Peculiar Bitters, is, of course, indispensable in the practice of medicine. Owing to its miserable taste, it is, unfortunately, not receiving as wide an application as it fully merits. We are all familiar with its specific action in malaria, but it is also a sovereign remedy in pertussis, pneumonia with delayed resolution, and in irregular or chronic grip. I am not prepared to say whether or not the brilliant effect in these cases is possibly due to some latent malarial disposition. Its miserable taste, as already stated, often precludes its administration to young children, for disguise it as you may, quinine will ever taste after quinine as long as there is quinine in the mixture. Some time ago (*N. Y. Medical Journal*, Oct. 23, 1897), I suggested the rectal administration of bisulphate of quinine, but, while this method works exceedingly well in hospital practice, it is not very ideal as a routine procedure. Where prompt results are desired we do best by giving it by mouth. The bisulphate is dissolved in water and rendered at least acceptable by the addition of *extractum glycyrrhizæ* and *syrupus acaciæ*. In severe cases of malarial fever, characterized by excessive vomiting and pronounced nervous symptoms, we have to resort to the hypodermic. Five grains of quinine hydrochloride dissolved in fifteen drops of hot water forms a suitable dose and may be injected intramuscularly, under most careful aseptic precautions, two or three times daily. In pertussis quinine bisulphate may be given in one- or two-grain doses every two to four hours, whereas one or two large doses of quinine usually suffice to hasten resolution in pneumonia or grip. Children over five years of age can often be induced to swallow chocolate coated tablets.

Of the numerous iron preparations in the pharmacopœia I prefer the tincture of chloride of iron, the solution of peptomanganate of iron, the syrup of the iodide of iron, and the dried sulphate. Iron is always useful for children and especially infants fed exclusively on milk, which, as you know, is poor in iron, and the solution of peptomanganate of iron will be found to act exceedingly well in all simple anemias of infancy. The tincture of the chloride of iron is usually prescribed as a styptic and hematinic in tonsillar affections and is advantageously administered in one- or two-drop doses in combination with the tincture of myrrh, potassium chlorate, and glycerin. This mixture adheres more or less closely to the tonsils and thus exerts its astringent effect upon them, often dispensing with gargles and local applications. The syrup of the iodide of iron is an ideal hematinic tonic in children, more especially in secondary anemias following or complicating acute infectious diseases, rachitis, and divers forms of glandular enlargement. In the so-called scrofulous affections it often

acts almost specifically, more particularly if combined with codliver oil. We have ample reason to believe also that this preparation, in addition to local attention to the nasopharynx, is frequently instrumental in reducing or even entirely removing adenoid vegetations, and its administration may be highly recommended to children, who, notwithstanding the operative removal of their adenoids, continue to suffer from persistent catarrh of the respiratory tract, and show a marked disposition to repeated recurrence of the adenoids. Finally, it is worth emphasizing that owing to the destructive effect of liquid iron upon children's teeth, whenever possible, powdered iron with a little sugar or in tablet form should be given instead.

The selection of a stable and palatable phosphorus preparation is quite a problem, hence its use in children is usually limited to its derivatives. The syrup of lime and soda hypophosphites will be found particularly beneficial in rachitis and associated affections, such as tetany and eclampsia infantum. It may advantageously be combined with syrup of the iodide of iron and codliver oil, which latter preparation, contrary to all expectations, is taken by young children with considerable delight.

Mineral Acids.—Insufficient attention is being paid to the medicinal properties of mineral acids. Aside from its usefulness in an acidity, dilute hydrochloric acid will be found extremely serviceable in all protracted fevers, such as typhoid, and tuberculosis. In anorexia of children dilute hydrochloric acid combined with essence of pepsin and small doses of *nux vomica* often works wonders. The dilute nitromuriatic acid in from two to five drops, well diluted, is indicated as a preventive of the so-called bilious attacks, characterized by recurrent vomiting, headache, and catarrhal jaundice, and the syrup of hydriodic acid is an invaluable remedy in all chronic bronchial affections of children, more particularly unresolved pneumonia and asthma.

Alteratives.—Arsenic, iodine, and mercury form the standard remedies of this group and if given in ample doses are invariably productive of excellent results. The use of arsenic in children is generally limited to chronic blood affections and chorea. In blood diseases arsenic should be administered in combination with iron either by mouth or hypodermically where prompt action is desired. For this purpose iron arsenate, from gr. $\frac{1}{4}$ to gr. 1, will be found particularly beneficial. From time immemorial arsenic has been lauded as a specific in chorea, and all of us have had occasion to corroborate this view. It is well to bear in mind, however, that arsenic is practically useless in the so-called rheumatic or infectious variety of chorea which calls for absolute rest in bed and salicylates, and may prove to be a very grave affection if procrastinated by arsenic treatment. In the neurotic type of chorea Fowler's solution may be pushed to its full physiological effect, provided the urine is carefully watched for a possible renal irritation. Fowler's solution in small doses seems also to enhance the therapeutic value of the bromides in the treatment of epilepsy.

Except in syphilitic affections, the syrup of the iodide of iron or hydriodic acid should be given in preference to potassium and sodium iodide. Moreover, it is worth reiterating that the iodides *per*

se, i. e. without mercury, will never cure syphilis, be it congenital or acquired. Hence the sooner mercury is resorted to, the better for the patient. The iodides may be rendered more or less palatable by means of peppermint or orange-flower water and simple syrup, or fluid extract of sarsaparilla and water.

Mercury, the specific in syphilis, may be administered to children by inunction, fortified by protoiodide of mercury internally. Five to ten grains of a 50 per cent. unguentum hydrargyri in lanolin rubbed in thoroughly once a day, and from 1-16 to 1-12 gr. of protoiodide of mercury three times daily will show beautiful results in a very short time. In the beginning of the treatment it may be necessary to administer a few drops of paregoric daily to allay intestinal irritation. In newly born infants with congenital syphilis we may at first order, gr. 1-10 of calomel every three hours and follow it up with the aforementioned remedies a few weeks later. There is very rarely any occasion in children to use more vigorous methods of treatment.

Antipyretics and Antirheumatics.—Water internally and externally is the best antipyretic in children. Whenever the temperature is ephemeral in character, as for example, in indigestion, tonsillitis, and the like, a cold sponge or pack answers the purpose admirably. On the other hand, when the temperature is continued and recalcitrant an effort must be made to influence the cerebral heat center, and this is best accomplished by means of warm tub baths. They tranquilize the nervous system, equalize the circulation, produce diaphoresis, and reduce the temperature without shock or depression. However, in highly nervous children antipyretic drugs, such as phenacetin, antipyrin, etc., also are indicated, and if given in moderate doses at long intervals are perfectly harmless. They may be made fairly palatable in syrupus acaciæ and orange-flower water. It may here be emphasized that a moderate dose of an antipyretic will often promptly control an attack of convulsions in children, at any rate long enough until its cause has been determined and appropriate remedies employed for its permanent removal. It is well to remember also that small repeated doses of antipyretics, more particularly pyramidon, will frequently subdue grotesque choreic movements where the usual treatment utterly fails. The specific effect of salicylates in rheumatic affections is too well known as to require reiteration on my part. It may be noted, however, that salicylates are tolerated by children in larger quantities than by adults, and if administered with a little caffeine sodium benzoate or strophanthus are perfectly free from depressing after effects. On many occasions I have had the opportunity to convince myself, as well as others, of the distinct abortive powers of sodium or ammonium salicylate in acute poliomyelitis. In my opinion it is more efficient even than immune serum. The salicylates are also invaluable in all acute infectious diseases and whenever you are in doubt as to what medicine to prescribe, you'll almost invariably strike it right by selecting this remedy. It also has the good quality of being palatable.

Hypnotics, Anodynes, and Antispasmodics.—The selection of pleasant hypnotics and anodynes is rather difficult, and perhaps fortunately so, since their

effect upon the delicate infantile organism at best is more or less deleterious. Very recently I was consulted to see a newly born infant supposedly suffering from atelectasis pulmonum. The baby was in profound stupor, its pupils markedly contracted, its breathing from ten to twelve per minute and pulse from forty to fifty per minute and barely perceptible. It refused to nurse and swallowed with difficulty. The family physician informed me that the baby had been sneezing and coughing, and to relieve the anxiety of the parents, he prescribed a cough mixture containing five minims of paregoric in each dose which was administered every two hours. Obviously we were dealing with a case of opium poisoning. By promptly directing the treatment against it the infant recovered very rapidly. The safe dose of paregoric for children is one drop for every year of the child's age, and one-tenth of this quantity when the tincture of opium is prescribed. In gastrointestinal affections where an opiate is indicated preference should be given to Dover's powder (one-tenth of a grain for every year of the child's age), because of the beneficial effect of ipecac it contains; and whenever vomiting precludes its administration, you will often find an opium suppository to act admirably. Where very prompt action is desired, as for example, in cholera infantum with profuse vomiting and purging, we may advantageously resort to a hypodermic injection of morphine (gr. 1-60), and atropine (gr. 1-600). Morphine and atropine hypodermically are occasionally indicated also in other acute diseases. Some years ago ("Practical Pediatrics," Gratzner and Sheffield, 1905, p. 184), I called attention to the marked efficacy of morphine and atropine in uremic convulsions of children and have employed it repeatedly since, improving, however, on this procedure by performing also lumbar puncture in conjunction with it. I first tried this combination on a seemingly hopeless case of uremia complicating scarlatinal nephritis that was accompanied by total amaurosis of both eyes, and had resisted every other method of treatment for six days. The effect of the hypodermic was almost magical. In respiratory affections codeine and its similar opium derivatives are the drugs par excellence. Whenever a hypnotic is indicated, codeine added to bromide will act by far better than the newer coal tar products. The use of spasmodics in children is somewhat limited. In olden times belladonna was looked upon as the *sine qua non* in pertussis. It was pushed to its full physiological effect—until the child was practically blinded. We know better today. Belladonna will be found useful, however, in ordinary catarrhs of the respiratory tract with profuse mucous discharge and in rhinitis of infants when the nasal discharge interferes with nursing. In combination with codeine, in the form of suppositories, belladonna is of particular value in irritable bladder, strangury, and tenesmus, and also acts nicely as a palliative in catarrhal appendicitis, when medication by the mouth is contraindicated. We may choose hyoscyamus instead of belladonna; in fact, there is no better antispasmodic and anodyne in dysuria accompanying cystitis than hyoscyamine sulphate. The dose is gr. 1-800 for every year of the child's age, dissolved in syrupus altheæ and water.

Stimulants.—Practically all stimulants are unpleasant in taste and require skillful compounding to render them palatable. Glycerin and the elixir digestivum compositum serve best in this direction. Strychnine and strophanthus are indicated in almost all infectious diseases of children and should be administered early rather than late. In the early stage of the disease the dosage, of course, should be small. Gr. 1/300 of strychnine and $\text{m}\bar{\text{q}}$ 1 of tincture of strophanthus will ordinarily serve the purpose admirably. I believe it is a mistake to leave stimulation in pneumonia to the very end, and I have made it a rule to give strychnine and ammonium carbonate or liquor ammonii anisatus the first three days of the disease, strychnine and strophanthus the following two or three days, and digitalis and alcoholic stimulants in the last days, when the cumulative effect of the pneumonia toxin is most apt to undermine the cardiac muscles. In urgent cases we are often called upon to add caffeine-sodium benzoate, and even adrenalin. It is always a good plan to provide the nurse with an ample supply of quick stimulants for an eventual emergency during the crisis, and I am able to assure you that at least in one case this intensive preparedness has worked wonders. About two years ago I was invited by Dr. K. to see a nine-year-old boy suffering from grippal, so-called wandering, pneumonia of two weeks' standing and complicated by double otitis media. As the patient was extremely weak and showed distinct signs of myocardial involvement, I suggested to the doctor to supply the nurse with three additional hypodermic syringes, one containing ten drops of adrenalin, the other one five grains of caffeine-sodium benzoate, and the third one 1/30 of a grain of strychnine—to be on guard against sudden heart failure. The next day another consultant was called and the day following a third one. This excellent clinician, in his laudable effort to erudite the cause for the delayed resolution directed the nurse to sit the boy up in bed in order that he might examine carefully the posterior portions of the thorax. While doing so the patient suddenly flapped backward, his jaws dropped, his pupils dilated, and his heart stopped beating, in short, he seemed as dead as a doornail. The physicians became terrified, mortified, and left the sick room to convey to the child's parents the dreadful message of the unfortunate event. In the meantime the nurse recovered sufficient sense to proceed with the simultaneous injection in the boy's arm of the three aforementioned reserve stimulants. To her great delight she soon noted a slight twitch of his mouth and heard a faint fluttering of his heart, and in another few minutes the boy was himself again. Resolution set in the following day. For a number of years past the profession has put a great deal of reliance on sterile camphorated oil as a powerful stimulant, more especially in pneumonia. I have used it extensively and am still resorting to it occasionally, but must frankly confess I have never been convinced of its utility and often felt that the sorely tried patient ought to be spared the pain and discomfort almost invariably associated with its hypodermic administration. Indeed, I fear that the needle has been recently grossly abused, be it in the subcutaneous injection of drugs or in that of an unlimited

number of inert vaccines and serums. I hope these remarks will not be misunderstood. While I firmly believe in the life-saving properties of antidiphtheritic and antimeningococcus serums and the like, I cannot help but feel that the profession is entirely too credulous regarding vaccines. A few days ago I came across a child with whooping cough who had received nineteen injections of pertussis vaccine!

In treating heart disease, it is well to remember that while digitalis is the indispensable remedy in chronic cases with "ruptured compensation," it is more or less harmful in acute heart disease, with compensation intact, when an ice bag to the precordium and small doses of codeine with or without sodium salicylate are indicated.

Heart Sedatives.—If ever there were any need for heart sedatives in children, we could readily get along with a minute dose of morphine or its derivatives, or possibly some coal tar product, such as pyramidon. Aconite, the standby of the homeopath, like digitalis, is a dangerous drug in the hands of the inexperienced. The real indication for aconite is supposed to be sthenic fever, and there are not many children too vigorous while sick. However, in homeopathic doses and well diluted it probably can do no harm.

Emetics.—No great effort need be made to disguise the taste of emetics. The wine of ipecacuanha, requiring but small doses, should be preferred to the syrup, and whenever emesis is very urgent a hypodermic injection of from gr. 1/12 to gr. 1/16 of apomorphine will prove most satisfactory. It is to be regretted that emetics are dropping into disuse, for many a case of acute indigestion in children could promptly be arrested by swift emesis. It may be worth mentioning also that moderate doses of ipecac are invaluable in whooping cough with prolonged suffocating paroxysms, thus by emesis imitating nature in aborting the attack.

Expectorants.—The selection of suitable expectorants requires good judgment. It is useless, in fact harmful, for instance, to prescribe stimulating expectorants, such as ammonium chloride or carbonate, in cases of persistent coughing arising from nasopharyngeal or laryngeal inflammation. We should rather be inclined to allay the source of irritation by local measures and administer sedatives to relieve the cough. With this object in view excellent results are usually obtained from daily instillation of from 2 to 5 per cent. of argyrol or silvol in the nose and the internal administration of creosote carbonate and codeine, well mixed with glycerin, mucilage, and water. On the other hand, when dealing with an harassing cough in acute bronchitis or pneumonia in which the expectoration is very adhesive and cohesive, scanty in amount, and hard to raise, a stimulating expectorant, with or without wine of ipecacuanha or the compound syrup of squills, in the majority of instances will prove beneficial to the patient by assisting nature to rid the lungs of effete material and save the patient's energy for the terrible battle ahead of him. In chronic bronchitis and unresolved pneumonia satisfactory results are frequently gotten from ammonium iodide, gr. $\frac{1}{2}$ to 1 for every year of the child's age, every three or four hours, or the syrup of hydriodic acid or syrup of the iodide

of iron. The iodides are very useful also in the exhausting cough accompanying non-compensating heart disease, and may advantageously be combined with digitalis and an occasional dose of some morphine derivative.

Diuretics and Diaphoretics.—Water is the most palatable and in large quantities the most efficient diuretic in bladder affections. If given hot and sweetened with sugar it is also an active diaphoretic and should be given preference to offensive diaphoretic mixtures, whenever possible. When drugs are needed, sweet spirits of nitre, potassium acetate, and potassium citrate generally serve well both as diuretics and diaphoretics. Potassium citrate in combination with hexamethylenamine acts specifically in pyelocystitis. Considerable caution, however, is commended in the continued administration of the latter owing to its tendency to produce hematuria. Another excellent preparation is sodium benzoate, which, as I fully emphasized many years ago (*N. Y. Medical Journal*, June 30, 1900) forms an ideal diuretic, diaphoretic, and expectorant in the group of symptoms frequently encountered in acute influenza. Diuretics are practically useless, nay, often harmful, in acute nephritis while the urinary tubules are obstructed by the inflammatory changes. In such cases we do much better with active diaphoresis by means of packs and hot baths and intestinal flushing—to rid the system of effete material without overburdening the renal function. On the other hand, in subacute and chronic nephritis, diuretics must be resorted to whenever the excretion of urine is diminished and a tendency toward dropsy becomes manifest. In such cases the liquor ferri et ammonii acetatis seems to act exceedingly well. If, however, the dropsy is extensive and of cardiac origin we always have to fall back on digitalis and strophanthus with or without diuretin or theocin sodium. Another indication for free diuresis is pleurisy with effusion, especially if the medication is coupled with complete abstention from all fluids in the diet. Under these conditions nature seems to absorb the fluid from the pleural sac to replenish the needs of the human economy.

Laxatives and Purgatives.—We are all too familiar with the action of castor oil, calomel, and phenolphthalein to require any detailed discussion. Attention may here be directed to the fact that there is no particular reason for giving calomel in divided doses and bothering the child unnecessarily. Any baby can stand a grain of calomel without much ado. Effervescent citrate of magnesia is contra-indicated where there is a tendency to vomit, the milk of magnesia being by far preferable. Purgatives and hydragogues are indispensable in acute nephritis and dropsical effusions, when the kidneys are unable to perform their function. Unfortunately, however, all of these preparations are very disgusting in taste and require large quantities to produce the desired effect. I find that Rochelle and Epsom salts may be rendered fairly palatable by the addition, to a saturated solution, of about a third of its quantity of glycerin and a few drops of aromatic spirit of ammonia. The mixture may then be administered in teaspoonful doses at frequent intervals. The infusum sennæ compositum may prove useful in some cases, but we must see to it that it is freshly prepared. In treating chronic constipation

of children our efforts in the direction of regulation of the diet and induction of regular habits will only too often fail and we are frequently called upon to advise a suitable laxative. I believe that malt extract with olive oil or cascara will answer the purpose in the majority of cases. The value of mineral oil in chronic constipation is greatly exaggerated, at least as far as its efficiency in children is concerned.

Intestinal Astringent.—Most of us still recall the sad time when during the summer months every pharmacist was stocked up with a large exhibition of summer-complaint—mixtures to meet the great demands of the season. Fortunately, with our advanced knowledge of the causes of the summer diarrheas of infants and the methods of prophylaxis there is no longer any excessive demand for such preparations. However, we have not as yet reached the millennium in infant feeding and hence are still called upon to prescribe the time-worn, yet efficient, bismuth and chalk mixtures. Ordinarily I prefer bismuth subcarbonate to the subnitrate and direct to give the patient from ten to twenty grains after each evacuation. In this manner we are able to control the dosage in accord with the severity of the diarrhea. As already stated, in colitis and cognate affections, opium and ipecacuanha will be found to act most satisfactorily. Dover's powder may be made palatable by the addition pulvis aromaticus. The different tannin preparations are worthy of trial only in chronic enteric affections, but here greater benefit will be derived from local treatment, more particularly daily intestinal irrigations with $\frac{1}{4}$ to $\frac{1}{2}$ per cent. of nitrate of silver—in addition to an appropriate diet. Bicarbonate of soda is, of course, the specific in diarrhea due to acidosis or fat indigestion, and should be administered in large doses by mouth as well as per rectum.

Gastric Sedatives.—Last in line but foremost in importance are the gastric sedatives, since with a highly irritated stomach, when all food or medication is promptly ejected, even a very mild disease, *per se*, is most apt gravely to undermine the baby's power of resistance. Hence the importance of first of all settling the stomach. In the majority of instances this is readily accomplished by one large dose of sodium bicarbonate, let us say, from thirty to sixty grains in water and followed up by smaller quantities of bicarbonate of soda and subcarbonate of bismuth with or without calomel. Good results are often obtained also from the different medicated waters, such as lime, peppermint, and bitter-almond water in cracked ice, or $\frac{1}{20}$ of a drop of tincture of iodine well diluted. In recurrent vomiting lavage is indispensable and in some cases we may even have to resort to a hypodermic injection of morphine. Of course in all cases of severe vomiting careful attention must be given to its etiology, more particularly involvement of the appendix or brain.

In administering medicines to children, it is often helpful to divide the full dose in several small doses, if need be, giving it drop by drop until the whole teaspoonful has been taken. In this manner even a most irritable stomach will often retain the medication, whereas it would otherwise reject it.

In conclusion let me suggest the following general rules to facilitate the selection and administration of drugs to children:

1. Never prescribe any medicine unless you are convinced of its necessity; if only a placebo is required, prescribe a palatable adjuvant.

2. Never prescribe a medicinal preparation requiring a large quantity, when a small one of the same or an equally as useful a drug will do the work just as efficiently. Thank Heaven, the time is passed when the greatness of the physician stood in direct ratio to the quantity of the concoction he ordered.

3. Never prescribe a painful therapeutic procedure or a nauseous mixture when the patient will do equally as well—and surely much better—without the unnecessary pain and annoyance.

ENTEROPTOSIS OR EXOPTOSIS?

By A. L. BENEDICT, A.M., M.D.,

BUFFALO, N. Y.

CAPTAIN, M.R.C., U.S.A.; CONSULTANT IN DIGESTIVE DISEASES, COLUMBUS HOSPITAL; ATTENDANT, MERCY HOSPITAL; EDITOR "BUFFALO MEDICAL JOURNAL."

ENTEROPTOSIS literally means a sagging of the insides, or inwards, but as these terms, in either Greek or English, are popularly applied especially to the intestines—the word showing the same tendency in Latin—and as in medical nomenclature, the stem *entero-* tends to be still further limited to the small intestine, enteroptosis may have a general significance equivalent to splanchnoptosis or sagging of the viscera or may be used in a more or less limited sense.

With the possible exception of blepharoptosis, there is a general agreement that all ptoses apply to laxity of the supports of organs, manifesting themselves as a sagging or descent of the organ as a whole in the standing posture. In regard to the stomach, there is, however, an unfortunate tendency to confuse true ptosis, that is to say, a displacement of the whole organ, whether normal in size or dilated, with the inevitable descent of the greater curvature which occurs when the organ is dilated, even when its upper portion is held in the normal position. With regard to enteroptosis in the limited sense of a sagging of the small intestine, it may be questioned whether it is possible, short of inspection by celiotomy, even by very careful and expert use of the *x-rays*, to determine whether the coils occupy their normal place or not in an apparently normal abdomen and whether, with the exception of the duodenum, the first part of the jejunum, and the ileocecal valve, the supporting structure, namely the mesentery, will not, without intrinsic abnormality, allow the bowel to conform to the position and capacity of the abdominal cavity as a whole.

Without entering into a discussion of the pathology, etiology, and diagnosis of enteroptosis, either in its limited or general sense, it may be pointed out that the conception of the term, *-ptosis*, should, on the one hand, be sharply differentiated from variations in size and shape of the organ itself, and, on the other hand, equally sharply discriminated from inevitable changes of position due solely to skeletal, muscular, and connective-tissue abnormalities of the enveloping body walls; whether we admit or dispute that owing to the latter abnormalities, a gradual and equally inevitable stretching or adjustment of the visceral supports has occurred.

In other words, while we may readily admit that the changes in the ligamentous supports of viscera which tend to allow ptosis in the standing posture are more or less analogous to relaxations of the tissues of the organs themselves and to those of exterior structures, there are problems in pathology, etiology, diagnoses, and even therapeutics, that require a discrimination in use of terms. Thus, assuming that we can in all instances map out the position of an organ accurately, the fact that it does not conform to the ideal location does not necessarily justify the word ptosis.

A good deal of the literature on splanchnoptosis is blemished by the failure to discriminate between genuine sagging of the viscera, due to faults of their supporting structures, and disturbances of visceral orientation, due to departures of the body wall from the normal. Hence the title of this paper. This failure of discrimination may be due merely to failure of conception or to lack of diagnostic skill, or it may be due to a definite desire to apply such terms as enteroptosis to exterior defects or abnormalities and to recognize these conditions as a genuine etiologic factor. In the latter case, the matter is one of definition. The writer believes that the term ptosis is too significant and too firmly fixed, so far as general conceptions go, to be changed. But, if it is to be used to designate, in a very general way, any kind of disarrangement of the viscera, due to exterior as well as interior conditions, then we must coin a new term to designate ptosis due to faults of the visceral supports themselves and must, especially with reference to treatment, make a sharp subdivision of nomenclature.

Some discussion is pertinent as to exoptosis, a word which is not intended for presentation as a medical term of permanence, but simply for convenience in this article.

The Venus Type.—Most elaborate articles on enteroptosis in the non-discriminating sense borrow the illustration or enumerate the dimensions of one of the classic Venuses. However pleasing to the eye, a Venus is not, strictly speaking, a feminine type. That is to say, it does not represent the shape of the average woman, civilized or uncivilized, it does not represent, item for item, an average of scientific observations of actual dimensions and proportions observed in health. The breasts, the abdomen, and the general deposit of fat do not conform to actual expectations of either the nullipara or the parous woman of the apparent maturity of the Venus. If a classic Venus were met in modern costume, she would be considered "dead ripe" in development and dangerously prone to obesity and its sequelæ. A thin woman, one with a few additional pounds of fat, one with disproportionately longer or shorter arms and legs, one with smaller breasts or those showing the deformities of lactation, one with a different shaped thorax short of actual deformity, even one with more or less muscular development under present conditions is, from the scientific medical standpoint, just as normal as a Venus.

No Proportionate Standard of Feminine Form Possible.—A very little reflexion suffices to prove that there can be no standard of form if we admit the normality of differences in height and it would be absurd not to do so. The female pelvis must, if

serious obstetric abnormality does not exist, remain of very nearly the same absolute size in its various diameters without regard to height. In plain language, the tall and the short woman, if normal in skeletal development, must be of very different shape. This difference applies not merely to the pelvis but, on account of differences in muscular power required for moving different weights, to the legs and the entire locomotive structure.

Similar remarks might be made with regard to masculine form, but, owing to the absence of the obstetric factor, the same importance does not apply to male form as to female. However, it is a matter of everyday observation that the greatest differences exist in stature and in proportions, as of height of trunk and of legs, without appreciable influence on the general health, not to mention the question of splanchnoptosis.

The Enteroptotic Type.—The flat-chested, round-shouldered, long-legged, skinny, breastless girl with rather protuberant abdomen has been depicted so frequently that it is unnecessary to reproduce the type. Many authors have been candid enough to illustrate this type with the note that splanchnoptosis did not exist. As a matter of fact, this type is very common and does not subject the individual to the social handicap that might be expected. Setting aside esthetics, it may be questioned whether this type is distinctly abnormal. Studies, not very recent, have surprised the profession into the admission that it is rather the round than the flat thorax that predisposes to tuberculosis of the lungs. Such girls and such young men are often vigorous, even athletic, and the latter often bear up well under stress of military life. The omoptosis is real, but enteroptosis in any true sense may or may not be present—in the writer's experience it is not especially apt to be demonstrable in this type. As the individual becomes more mature, better nourished, and takes on even a few pounds of fat, the center of gravity of the trunk is altered so that, almost without effort and certainly without shoulder braces, or abdominal bandages, the shoulders become square and the abdomen is held normally.

The Broad, Flabby Type.—In persons of this build there is obviously more room in the thorax and abdomen for the various viscera and there is a natural tendency toward over-nutrition, at least in the sense of allowing a deposit of fat, which further drags upon the abdominal wall, although the pendulousness of the abdomen is rather apparent from the thickness of the wall than real as affecting the abdominal cavity. Pregnancy produces more permanent results in the deposit of fat and relaxation of the abdominal muscles. As to the pelvic organs, whose ptoses are usually designated according to a different nomenclature, the writer is unable to state further than that such persons are not especially apt to show true splanchnoptosis. Extreme degrees of nephroptosis are, indeed, far less common than in tiny, narrow-waisted women. The projection of the gastric area on the skin at first sight suggests gastropptosis, but this is due merely to the relatively larger size of the viscera, the smaller deviation of its major axis from the horizontal, corresponding to the general contour, the relatively high position of the umbilicus, and the "spread" of vibrations in projecting the stomach on

the surface of a thick abdominal wall by percussion. The intestines naturally assume a slightly different position in such an abdomen, for exactly the same reason that they would spread out differently in a broad pan at a necropsy as compared with their disposition in a high, narrow pail. The liver is broader and flatter than in a narrow-waisted person and it may, without any greater relaxation of its supports than corresponds to the general tonicity of the tissues, project slightly below the costal arch, in which case palpation through a thick abdominal wall exaggerates the conception of its downward extent. Comparing narrow with broad chests, as a rule the former more than cover the liver, while the latter may not quite do so. It is not meant by all this that a person of this type is immune to splanchnoptosis, but that no general predisposition to such a condition exists.

The Narrow-Waisted Type.—Artificial constriction of the waist is, by decree of fashion rather than hygiene, a matter of a generation ago. This was emphasized by the writer a short time ago at Atlantic City by the appearance of a fairly young woman with the waspwaist of the early '80's. The amazement and interest of the younger women was the best evidence that tight-lacing is practically a dead issue—except the transient tight-lacing of the obese. But there is a natural narrow-waisted type, more common in small women, and accentuated by the absolutely nearly identical and relatively larger pelvis. In this type there is an inevitable shortage of room at the waist for various vital organs. Whatever the original cause of the condition—and the histories are positively against artificial deformity—the liver is bell-shaped, there is seldom good pulmonary and cardiac power, the stomach is small, even to such a degree that adequate diet on food of average bulk is something of a problem, the stomach axis is nearly vertical and hence there is a tendency both to dilatation of the lower portion and to the development of true gastropptosis. One or both kidneys are often—not always—quite freely movable. The nephroptosis may be discovered after pregnancy or a traumatism, but it is so common in this type that it must be regarded as preceding such causes, especially as it is often demonstrable in nulliparæ. In fact, it is questionable whether a single case of movable kidney exists that has been positively demonstrated to have been due either to pregnancy or to traumatism, by "before and after" examinations. On the other hand, the renal movability is not congenital, since the proportionate number of cases found in routine examinations of infants is small—1 to 2 per cent., even including the slight movability probably due merely to the natural greater elasticity of immature tissues—whereas the female series after puberty give proportions of about 5 per cent.

Relation of Abdominal Deformities and Lesions to Splanchnoptosis.—Diastasis of the recti, large ventral herniæ, especially when so large as to present virtually a second abdominal cavity, marked spinal deformity, lordotic or kyphotic, extreme trophy of the abdominal muscles, possibly of the fasciæ also, and without even the protection of a reasonably thick fatty layer, inevitably result in greater or lesser distortion of the normal disposition of the viscera. In some instances the condition

is literally a splanchnoptosis, especially an enteroptosis, in others it is difficult to designate the condition by a formal term. Sometimes the intestines have simply followed lines of diminished resistance compatible with perfectly normal supports. For instance, when the intestines have promptly poured through a large hernial ring or through the slit between the recti after labor, we are not warranted in assuming any essential failure of the supporting structures of the intestine itself. But, in practically all cases of gross deformity or traumatic yielding of the body wall, even an originally normal visceral support must eventually yield to the constant forces of gravity and intramural pressure. Without quibbling as to whether the term splanchnoptosis is literally correct or not, such cases must be differentiated from those in which, without gross failure of support by the body wall, an intrinsic failure of supporting tissues occurs.

For the sake of focusing attention on a single point, it has been thought best to omit extensive considerations of splanchnoptosis. This term and its subdivisions should be logically and critically applied. Actual demonstration of position of any organ should precede a diagnosis and the position of one organ should not be inferred from that of another. If this rule is followed, general splanchnoptosis will be found to be quite a rare condition, and plural splanchnoptosis will be found to be somewhat uncommon and by no means regularly associated, nor following plausible a priori conceptions. The ptosis or sagging itself, in the literal sense, is an accident of gravity. The essential factor is the lack of competence of the visceral supports—this general and non-technical term being preferred for our purposes to strictly anatomical terms, in order not to limit the attention to any one viscus. Such lack of competence is demonstrated by movability or displacement of each organ, as a whole. In all cases in which the orientation of the viscera departs from normal standards, a sharp distinction should be made between intrinsic ptosis and deviations which are by no means due to internal conditions but to those affecting the general contour and limits of the body wall. So long as no physiologic or pathologic result occurs, a misshaped body is, from the standpoint of internal medicine, no more abnormal than a homely face with bad features. Exterior skeletal and muscular conditions, within reasonable limits, do not necessarily determine splanchnoptosis. They do not even predispose to it to the degree suggested by much of the medical literature. Therapeutic measures, especially of a mechanical or operative nature, should be directed toward the actual condition of exterior deformity, for its own sake, and not toward a suppositious internal condition.

228 SUMMER STREET.

Alcoholic Polyneuritis.—Juarros reports the case of a woman aged 38 who was addicted to the abuse of alcohol, ether, and morphine. Her father had been a syphilitic, but her own Wassermann was negative. She was attacked with what appeared to be rheumatism, but later there developed motor weakness and anesthesia with pains despite her morphine addiction. The pains ceased on suppressing the alcohol. There was some mental impairment, which suggested a possible Korsakoff's disease.—*El Siglo Médico*.

CUSTODIAL CARE OF ADDICTS.

By E. C. CHAMBERLAIN, M.D.,

NEW YORK.

SENIOR VISITING PHYSICIAN, CORRECTIONAL HOSPITAL, THE PENITENTIARY; ATTENDING PHYSICIAN, VANDERBILT CLINIC, NEW YORK CITY.

SOME attention is being given of late in the lay and medical press to the drug evil, and, as usual, there are some exaggerated statements of true conditions. However, the real facts are bad enough to demand the earnest attention of thinking men and women. That the drug evil exists and is a growing menace to particularly the young people no one will deny who is conversant on the subject, but when a physician stated some time ago that the U. S. Army contained 200,000 drug addicts that remark was from the alarmist point of view. Those of us who have served recently in the army and held important posts do not agree with the exaggerated opinion. For the benefit of those who may be alarmed, let them rest assured that the U. S. Army Medical Department has long been on the watch; certain drugs favored by addicts have not been permitted to be used for some years past in the Medical Department.

It is astonishing how little knowledge exists among the medical profession as to any course of treatment which may be of a curative nature. The fact is, the management of certain sanatoriums and certain physicians feel they have the only proper course of treatment. Upon reading the leaflets sent through the mails on the subject of a cure, it is noticed that any discussion of treatment is as a rule carefully avoided. It may be that it is left to be assumed by the profession that the stages of elimination, withdrawal, and rehabilitation are fully understood. The generous(?) instincts which prompt the frequent advertising propaganda sent out by some of our lay-medical institutions never lead to a word of help or cheer to the physician or addict, for whatever treatment is suggested is so camouflaged that the average physician learns not a thing, after all, except the address of the sanatorium. It is most unfortunate that in the past so little cooperation and effort has been made by our profession to combat or study the drug addict situation. Some interest has been aroused over the proposed law in New York City, and it is earnestly hoped that the war will not draw our attention from the subject. We have only scratched the surface so far as treatment goes, and certainly there is no specific, while the fact still exists that no two cases present symptoms exactly alike. The so-called reduction treatment might be mentioned, but I have seen so much harm done through this evasion of the spirit of the law as practised by an increasing number of physicians that the less said the better until the strong arm of the law takes hold of the situation and in some manner reaches these medical leeches. Whether the sufferer needs a physician, chiropractor, osteopath, or Christian Scientist, what cares the addict or his relations so long as he can be cured. Therefore, it is the cure, after all, that the patient wants, and one of the first steps in treatment is the elimination stage, the purpose of which is to reduce the physical need for the particular drug.

From the mass of data on treatment certain few

facts stand clearly forth as essential toward any cure of these unfortunates, and it matters not if they are from the lower or higher grades of society. During the elimination and withdrawal stages custodial care is most desirable and important and must be continued for at least ninety days longer while the patient is undergoing convalescent treatment and rehabilitation. The stage of rehabilitation must not consist of the easy-chair sun-parlor type, but of the most active and increasing exercise graded, of course, to suit the individual case. Any kind of physical exercise in the open air is most desirable and particularly of such a character as to interest the patient. It must be understood that the convalescent addicts are recovering from a real disease, certainly as much, if not more, from a physical as from any mental condition. This factor is being more generally appreciated than formerly. During this rehabilitation period, I believe that while custodial care is being exercised if it is of a military type it would be most beneficial. In a certain private sanatorium several addicts ended their lives last year through suicide by jumping from unprotected windows. Such an accident would be impossible in a properly constructed and conducted custodial institution.

No doubt exists in the mind of any one who has given thought and treated many of these cases, but that custodial care is all important and especially so if the patient is frequently assured that he is to be cured. Even when the patient is under custodial care, the ingenuity and cleverness displayed in obtaining the favorite drug is remarkable. In the first place, many of these cases are well supplied with money, even though they may be committed to a public institution. Money used as a bribe to smuggle in drugs will do naturally much damage in thwarting any medical efforts. Through the professional keenness of the resident physician, at the Correctional Hospital, Blackwell's Island, Dr. Thos. F. Joyce, cases have been discovered where letters were being chewed and swallowed which had been soaked in a solution of morphine. Picture postal cards contained powdered heroin deposited between the layers of paper. There are many other equally clever ways of importation known.

Patients of this class are entitled to every consideration, care, kindness, firmness, and attention, especially so during certain stages of the treatment, and the personality of the physician and nurses is a most important factor in obtaining successful results. In the Correctional Hospital, Blackwell's Island, at Riker's Island, and elsewhere, where several hundred each year are treated and afterward physically reconstructed, the results are most interesting and the benefits satisfactory. With the hearty cooperation of the Commissioner of Correction, Dr. James A. Hamilton, it is believed and felt that real constructive work is here now being done. To discharge the addict as cured after from seven to ten days, as is done in some city hospitals and private institutions, is only turning him loose to try it again. The addict has not had any chance to brace up physically or mentally and the result is physical and mental weakness and hence it is that so many return to their old habits. It has also been observed that where the addict has had several treatments the psychological effects are serious as it tends to

make them the most pessimistic of all mortals.

The Whitney Committee in its report to the present legislature recommended the procuring of funds to build State institutions for treatment of addiction scientifically without the prison atmosphere which now shadows the entire period of treatment. It is to be sincerely hoped that the Empire State will discover the necessary funds for this purpose. For the immediate treatment and the handling of these addicts of moderate circumstances and those that are really poor, the city might give over one of its numerous City Hospitals and operate it strictly for addiction cases and under proper custodial care. The department of correction has under construction two splendid sets of buildings, well removed from temptations and relations which, when completed, with the abundant acreage surrounding these units will give a wonderful opportunity for rehabilitation. The New York State law, as above mentioned, on control, sale, etc., of drugs which has been drawn with much care, will be of some aid in keeping down the drug traffic, but one thing is certain and that is until the Federal authorities enforce the Harrison Drug Act, or give us an effective national law, interstate traffic will do much to mitigate against a successful outcome of State control.

4 WEST EIGHTY-FOURTH STREET

SOME OBSERVATIONS CONCERNING THE STRUCTURAL AND RELATIONAL VARIATIONS IN THE UTERINE PERITONEUM.

By HOWARD CRUTCHER, M.D.,

TULAROSA, NEW MEXICO.

MOTION is the essence of life. Change, or alteration, is the standard by which the effects of motion are estimated. The various structures of the human body undergo changes not only of a nutritional character but also of their essential form and substance. The urinary bladder in a boy of five years is not what it is in locality or structure in a man of seventy. The human uterus is covered with a peritoneal coat. So runs the teaching. But it must be borne in mind that coverings of tissue are quite as variable, perhaps, as coverings of fabrics. The surgeon should be the last of scientific men to express surprise at changes of whatever kind. Nature herself is such a prolific maker of history that she pays no heed to the feeble efforts of man in the same field of labor. A thickened membrane here, an enlarged gland there, are Nature's methods of recording her doings within the human frame, precisely as a lake here and a mountain yonder are evidences of her handwriting in another sphere of her dominions.

Surgeons are familiar with the immense variations in the character of the uterine peritoneum, without always being able to assign an acceptable reason for such variations. In some instances the serous investment of the organ is as thick as heavy cloth and as elastic as young rubber. At other times it is as thin as fine silk and quite as frail. Occasionally extreme thinness is associated with high elasticity and great tenacity. Sometimes the peritoneum is more of a supporting structure than an investing membrane. Nothing short of actual

digital and ocular exploration will reveal such variations. The processes of reproduction, contrary to expectation, perhaps, appear to exert little or no influence upon the general character of the peritoneum. In a Langenbeck hysterectomy performed in a multipara of forty-seven the peritoneum was precisely in appearance what it was in the case of a virgin of thirty-three upon whom I performed the same operation. I have only seen the uterus at full term in the living subject four times, in three of which cases the investing peritoneum was freely movable over the tissues underlying it, while in the fourth case it was so immovably attached to the uterine wall that the deep wound made during a cesarean section had to be closed with a single layer of interrupted stitches.

The character of the peritoneal covering does, however, exercise a great and perhaps a decisive influence upon the fortunes of the uterus itself during the expulsive stage of labor. Lacerations of the uterine neck are too common, and are far too well known, to require comment. More penetrating lacerations, extending well into the body of the organ, are probably far less common and are certainly far less understood; but that such lacerations do occur admits of no question whatever. The dangers to life arising from an injury extending to the peritoneal coat and one extending through this coat, are not to be compared. Fatal bleeding might occur as readily in one case as the other, but the opportunities for other complications no less fatal in character would be multiplied incalculably. Careful students of uterine pathology well know that early miscarriages, possibly those occurring in the second and third months, sometimes produce very extensive lacerations of the cervix. Pressure of the fetal head being only one of the factors in uterine laceration of whatever extent, and the extent of the laceration not being proportionate to the size of the head, by what process of reasoning do we set up arbitrary limits for the extent of the laceration in any case whatsoever? There has been, it may well be feared, much loose reasoning and more faulty teaching concerning these matters. It is morally certain that many women have been lowered into their graves from spontaneous laceration of the uterus when some other cause has been assigned for their unexpected taking off.

Nor must it be supposed that the uterovesical and the uterorectal pouches are constant in character. I have opened the cavity of the peritoneum when incising a fluctuating pouch projecting well into the vaginal vault below the lower lip of the uterine cervix. When making the primary incision in performing hysterectomy for cancer of the cervix I have at times mistaken a gush of serum for an escape of urine, so deeply does the peritoneum press at times beneath the base of the bladder and forward into the superior fornix. When the peritoneum is greatly thickened and densely adherent to the body of the uterus the only safe method of proceeding upward is to follow minutely the muscular wall of the uterus and be guided by its fibers, avoiding if possible the mucous canal of the organ.

A word here may not be amiss concerning the Langenbeck operation for hysterectomy. This operation, as I understand it, consists in the removal of the uterus entire with the sole exception of its peritoneal coat, which is not violated at any point

save at the two utterly inconsequential Fallopian orifices; in other words, to employ a somewhat inelegant metaphor, of skinning the uterus from its neck to its dome without buttonholing the hide. It is perfectly clear that this operation is only possible in those cases in which the work of the surgeon has been laid out for him by natural conditions beforehand: the peritoneum must be sufficiently thick and elastic to permit extraordinary pressure without rupture. Clinically, in the light of modern teaching, the operation has no advantage whatever over other methods in every-day use. I performed the first Langenbeck operation in New Mexico on December 18, 1907, the patient regaining her feet within a week. The mere wounding of the peritoneum, and of the peritoneum alone, is of no more comparative consequence than is the wounding of any other tissue.

When the peritoneum, admittedly normal, presents as many variations as the ground under our feet and the clouds over our heads, it should assuredly occasion no surprise when that membrane, distorted by pathological changes, disappears entirely as a distinct structure. Fortunately the general principles of surgery are broad enough to guide us aright with tolerable precision in all regions of the body.

COOPERATION BETWEEN LIFE INSURANCE COMPANIES AND THE PRACTISING PHYSICIAN.

By THOMAS W. EDGAR, M.D.,

NEW YORK.

IT has befallen my lot during the past several years to be engaged in the physical examining of applicants for life insurance, both as a member of the medical department of an insurance company, and at present as a free lance. During this time I have come in personal contact with many practising physicians who are doing general work, attending to the various medical and surgical needs of their clientele. I have talked with these physicians as a personal representative of the insurance company regarding information relative to applicants for insurance.

I feel that my experience has been of such a broad nature that I may discuss the attitude of the lay physician toward the insurance examiner, and express an opinion as to what cooperation exists, and why more does not exist.

Life insurance examining today is a specialty. No physician taken from the ranks of general practice is capable of performing the duties of life insurance examining any more than the general practitioner is capable of doing special work without training. The successful insurance doctor must be trained; he must be taught to appreciate the meaning of perfect health; in other words, what constitutes the "physiological standard."

His medical course plus clinical experience have instituted in his mind the pathological, at the expense of the physiological. The general practitioner has observed individuals who, in the great majority of cases, are below par physically, and he is biased in his attitude toward the physiological when it comes to a physical test. The general practitioner sees the pathological, and through this as a

medium filters his diagnosis or his opinion; while the life insurance physician sees the physiological in the great majority of cases, and expresses his opinion on a definite concrete appreciation of the normal.

Thus we have the first antagonistic phase which is acting as a bar to cooperation.

From the above we may logically deduct that the insurance physician is a specialist in health, while the general practitioner is a specialist in disease, both striving for the same goal, "health," the former trying to prevent disease, the latter to cure.

It has been my fortune often to have my diagnosis in certain cases questioned by the applicant's family physician; and I have also recommended for life insurance applicants who have been pronounced uninsurable by other physicians, this difference of opinion being due to lack of standard and not to diagnostic ability.

The insurance examiner who is devoting his whole time to insurance work (1) appreciates and estimates the degree of health present in the risk; (2) He has learned that all deviations from the normal are not pathological but exceptions to the general physiological standard; (3) His prognostic sense, which has been developed by clinical experience, mortality tables, and personal contact with many risks, comes to the front, and allows him to express a definite opinion as to just what degree the applicant is off color.

The practising physician draws a sharp line of demarcation between the physiological and the pathological, and seldom allows for deviation as fostered by environment, occupation, age, etc. He makes his diagnosis because the physical findings are not normal according to his past experience in the clinics, in the hospitals, and in his practice. Thus his standard of health is biased by the pathological, and is not of great prognostic worth so far as longevity is concerned.

For this one reason and many others, cooperation, especially in diagnosis and prognosis, is lacking between the general practitioner and the life insurance physician. It is not intentional, but simply lack of one standard or control, and until all the physicians, insurance and otherwise, look to the same physiological standard as a basis for prognosis and diagnosis, we shall have this lack of cooperation.

766 WEST END AVENUE.

Medicolegal Notes.

Privileged Communications.—On January 6, 1913, the plaintiff's husband made written application to the defendant company for a policy of insurance on his life payable to the plaintiff, the premium for which was \$13 payable quarterly in advance. In his application he declared:

"That the policy herein applied for shall be accepted subject to the privileges and provisions therein contained, the said policy shall not take effect until the same shall be issued and delivered by the said company, and the first premium paid thereon in full, while my health is in the same condition as described in this application."

At the time of making such application he paid to the defendant's agent \$2, and received a receipt therefor, in which it was stated that the payment "is in no way binding upon the said company except that said company agrees to return the amount mentioned herein in case the company declines to grant a policy on the life of said applicant."

On January 9 he passed the required medical examination and a policy was issued on January 15. The policy was handed to the applicant, but he was unable to pay the premium therefor, and the agent told him that he was not insured until the balance of the first quarterly premium was paid. From that time until February 14 the agent repeatedly called upon the applicant for the unpaid premium, but it was not paid. On the morning of February 14 the agent received the unpaid premium by direction of the applicant at the house of his (applicant's) brother-in-law. On February 12 the applicant had a cold and a slight cough. At 12 o'clock on that day he said to his employer that he was not feeling very well and might stay at home an hour longer than usual, but would be back in the afternoon. He never returned to his work. On February 13 he was attended at his home by a physician. He was then sick. He was taken to a hospital on the morning of February 14, and died there of pneumonia February 20.

The plaintiff signed a certificate in proof of her husband's death and it was delivered to the defendant, accompanied by a certificate of the physician who attended him at the hospital. In her certificate she states that her husband's health was first affected February 12, and in answer to the question "What was the cause of his death?" she referred to the physician's certificate, and she also says therein that it is agreed that the certificate of the physician "shall be considered as part of proofs of death of insured."

This action was brought upon the policy, and the defendant alleged as a defense that when the first premium was paid to the company the applicant's health was not the same as described in his application, and that such fact was not then known to the defendant. The question as to whether his health was the same as described in the application was submitted to the jury and the jury found in favor of the defendant. The judgment entered upon such verdict has been unanimously affirmed by the appellate division. There are but two questions of law presented to us by the appellant: (1) Whether it was error to receive the testimony of the physician who attended the deceased on February 13, that he was then sick; (2) whether it was error to admit in evidence the affidavit and certificate of the hospital physician accompanying the certificate made by the plaintiff as a part of the proofs of her husband's death.

The prohibition against a physician giving evidence of matters within his knowledge, relating to a patient, is statutory. It is confined to information acquired in attending a patient in a professional capacity and which is necessary to enable him to act in that capacity. Code of Civil Procedure, § 834; *People v. Koerner*, 154 N. Y. 355, 366, 48 N. E. 730; *People v. Austin*, 199 N. Y. 446, 452, 93 N. E. 57.

The code section is not intended to prevent a person from testifying to such ordinary incidents and facts as are plain to the observation of any one without expert or professional knowledge, and without tacitly or otherwise inviting or receiving confidences by which the incidents and facts are or may be brought to light and obtained. It was therefore said by Judge Earl, with the approval of all the members of this court, in *Patten v. United Life & Accident Insurance Association*, 133 N. Y. 450, 453, 31 N. E. 342, 343:

"There is nothing in section 834 which prohibited the defendant from showing that Patten was the patient of the doctor; that he attended him as a patient, and that he was sick. Nor is there anything in that section which prohibited the doctor from testifying whether he was called upon to attend Patten professionally before or after the date of the certificate, or to tell how many times he attended him, whether daily or hourly, from the 19th day of April to the 16th day of May."

When the information obtained by a physician extends to the existence of an ailment, although not the subject of his attendance or treatment, but is acquired through an examination of the patient in attending him in a professional capacity, and the discovery of which was a necessary incident to the investigation made to enable him to act in his professional capacity, it is within the language and purpose of the Code prohibition.—*Klein v. Prudential Ins. Co.*, New York Court of Appeals, 117 N. E. 942.

Military Medicine.

MILITARY MEDICINE AT THE CANADIAN MEDICAL CONGRESS.

(From a Special Correspondent.)

HAMILTON, ONT., June 1, 1918.

ON Wednesday, May 29, there was a combined general session of the Canadian Medical Association devoted to a symposium on the returned soldier problem.

The first paper, by Lt. Col. Colin Russell, C. A. M. C., dealt with psychogenetic conditions in soldiers, their etiology and treatment. Psychogenetic conditions and the subdivisions of this type of disturbance were described and their etiology studied. It was pointed out that these conditions were the result of the conflict between the natural inherent instincts and the more lately acquired control of these instincts by the higher self. Psychogenetic means literally born in the mind and such conditions represent physical and mental disability. However, the futility of a refinement of classification was obvious, and suffice it to say that as Russell stated they range from complete blindness to complete mutism. These types appeared in epidemic form and occurred at the outcome of the conflict of deficient control of congenital origin as in mental deficiency, or due to lack of proper training, also owing to the natural exhaustion of the acquired higher control under prolonged strain. The defeat of the higher control and the abolition of the critical activities of the censor rendered the patient open to suggestions that met the wishes of the conquering instinct. Trench backache was the first of these conditions to appear in epidemic form, since which various types had occurred. In but few of the cases were pathological or physical signs to be observed. They mimicked true disease. For example, in simulated convulsive seizures the movements were purposeful, differing from true epilepsy in which the movements were involuntary. Conditions of this character formerly were termed hysteria and they really were forms of hysteria simulating all kinds of disability. The war was not responsible for the initiation of these conditions but had greatly aggravated them by arousing inherent instincts. The treatment should consist in repressing the usurping instinct and stimulating the higher control to perform the duties of their office in their usual normal manner.

Dr. J. H. Elliott of Toronto in the interim between the reading of this paper and the reading of the next paper read a list of the graduates and undergraduates of Canadian universities who had given their lives for their country and for liberty in the war and delivered an eloquent eulogy on their services. While the audience stood with bowed heads Dr. Elliott recited Dr. John McCrae's immortal poem, "In Flanders Fields."

Col. J. H. Cameron, C. A. M. C., of Toronto read a paper on general surgical observations with special reference to orthopedics. He discussed chiefly the history of orthopedics, particularly making mention of the men who had shone in the branch of surgery from remote times to the present time. He also made reference to a number of interesting and peculiar surgical cases, particularly among soldiers, that had come within his experience.

Lieut. Col. Hadley Williams gave an address on the surgery of nerve injury. His paper dealt solely with the surgical treatment of the divided nerve. The majority of the cases he discussed were nerve injuries he had witnessed at the front, caused chiefly by bullets and shrapnel wounds. He emphasized the necessity of rendering the wound aseptic before attempting to repair the nerve.

The place of physiotherapy in the treatment of the invalided soldier was the subject of a paper read by Lieut. Col. Robert Wilson, C.A.M.C. He related some of his experiences in the overseas hospitals while tending the wounded and in Canada when engaged in the work of fitting the returned men to take useful civilian positions. He discussed mainly the subject of organic nerve lesions and the success of physiotherapy in relieving and curing them. He stated that in a short time a course would be instituted in Toronto University in this important branch of medical treatment for the purpose of training medical officers.

Dr. Thaddeus Hoyt Ames of New York read a paper on the prevention of war neuroses or shell shock. Although Dr. Ames had not been to the front he had had considerable experience so far as observing cases of war neuroses was concerned. He had visited frequently hospitals in Montreal and Toronto in which such cases were being treated and had conversed often with medical officers who had been at the front. Therefore, he had gained a great deal of information on the subject and considered himself competent to express definite views with regard to the causation, the prevalence and treatment of war neuroses. He stated, as a fact, that shell shock did not occur in some regiments, nor in men who suffer from organic disease. Discipline was an important factor in keeping away shell shock, the routine of discipline so dominating the mind that there was little time for introspection. But discipline alone was not a sufficient preventive. In the first instance, when men were being medically examined for the army, those should be at once eliminated who were obviously of unstable nervous temperament, and equally as a matter of course those who were mentally defective or insane. Theoretically, discipline was an efficient means of preventing shell shock, but although it did a great deal in this direction, it was not all powerful. Traumatic hysteria was practically a thing of the past due largely to the teachings of Pearce Bailey. Much of the shell shock which had occurred at the front would have been avoided had the men been told by one who understood and in whom they had faith that fear was nothing to be ashamed of. Ames emphasized the fact that neuroses were unknown in some regiments, and this absence of shell shock was largely due to medical and junior officers. Some men were able to exert control over soldiers and authorities declared that shell shock was avoidable if the men in the ranks were properly taken care of. The line officers and the medical officers could keep away shell shock. They should assume responsibility for the welfare of the men and take a personal interest in them. The lieutenants and non-commissioned officers are most closely in touch with the men, and they should make it their business as far as possible to know all about them and treat them as human beings and not merely as cogs in

the machine. Change in the behavior of a man should be reported immediately. The line officers rather than the medical officers had the best opportunities for first noticing such a change. As soon as it was observed, the man should be given some other duty or employment to interest him and every possible means should be taken to distract his thoughts from himself. Reprimanding sharply so as to cause a reaction was sometimes effective. Chatting with some, joking with others and severely criticising others all answered the purpose. The officers must be keen judges of human nature and must use whatever means they deemed suitable to the temperament of the individual. The prevention of neurosis in a regiment depended almost wholly upon the officers. The confidence of the men must be gained and they must be encouraged. The officer's object should be to induce the man to get his troubles off his mind and he should speak to him in a friendly brotherly way. Medical officers had not the opportunities of the line and non-commissioned officers for gaining the men's confidence. In a limited way they had exceptional opportunities; at sick call for example, they had the opportunity of becoming acquainted with the inward workings of the human mind. A person sick is extremely open to suggestion, and the sick soldier is peculiarly so. Moreover he believes firmly in the medical officers.

Training the body and mind kept up morale. War tended to the unleashing of the primitive conditions, and the training of the soldier was of great value in holding these conditions in check and especially the condition of fear. Soldiers could be trained to control fear in the same way that they could be trained to restrain sex emotion. They could be taught that discipline was for the good of the State as well as for their own good. Soldiers should know the cause and origin of neurosis and should be instructed by medical officers that fear is a healthy normal reaction in the presence of danger.

Dr. A. W. MacCallum of Baltimore dealt with the question of the pneumonia of army camps. He said in part, that the epidemic form of pneumonia which had been prevalent in army camps differed from the ordinary types of pneumonia. In San Antonio, Texas, the disease had been studied. Also at Camp Upton and Camp Dodge, Iowa. The disease was not lobar pneumonia, but was caused by a hemolytic streptococcus, was of bronchial form, and gave rise to empyema. It was very deadly and epidemic. The pneumococcus of lobar pneumonia was now being very closely studied. There were other types of pneumococcus in the different parts of the world notably the Rand pneumococcus. Little had been learned concerning the clinical side of streptococcal pneumonia. The condition came on often after cold, frequently after measles, which had been very common, and also after scarlet fever. Exposure to cold was a predisposing cause. It ran a rapid course, marked by sore throat, swelling of the larynx, voice affected after deep ulceration of the vocal cords, dyspnea was present, and a great difficulty in gaining breath. There were râles everywhere and tubular breathing but not very distinct. The lungs became compressed with accumulation of fluid, flatness of the chest appeared. The fluid was slightly turbid of a straw-like color,

which became brown and later purulent and thick. Treatment was by means of aspiration or by resection of ribs and washing out with Dakin's solution. All cases ended in a high mortality. No really reliable statistics were available with regard to streptococcal pneumonia but MacCallum thought the death rate was higher than the figures indicated.

At autopsy there were several distinctive physical features which clearly differentiated it from lobar pneumonia. On section of lung large nodules were found which could be felt and which resembled miliary tubercles, and, indeed, had been mistaken for them. Sometimes these nodules grew as large as peas and were firm and quite hard. Fluid accumulated rapidly, adhesions often imprisoned fluid which made aspiration difficult. After evacuation, remnants of pus and abscesses became confluent and spread widely. Induration took place, thickening of the frame work of the lungs. The rapid infiltration of the tissues suggested to MacCallum the name of interstitial bronchopneumonia. The disease has been known for some time but the idea of connecting a hemolytic streptococcus with it was new. Most extensive experimental investigations with regard to the malady had been made. Careful bacteriological studies made at autopsies had revealed the fact that in all cases one organism had been found which was recognized as a hemolytic streptococcus. The results of research as regards the streptococci had been most meagre, they were most perverse organisms to work with. They grew in long chains matted together, agglutinated spontaneously.

In the course of the disease occasionally pericarditis was present, and abscesses but no septicemia. This statement had been contradicted, for other observers had found streptococci in the blood. Interstitial bronchopneumonia was a severe infection readily transmitted by personal contact, droplet infection, or spray from nose, mouth, or throat. Sterilization did not appear to stay its spread, while mechanical sanitation was almost impossible. Other forms of prophylaxis must be referred to with caution, vaccine had been made with which to fight it, but had not been applied because the disease was on the wane and therefore the test would not be satisfactory. MacCallum said that it was not only a serious disease but would demonstrate its epidemic nature and violence among the civil population.

In the discussion that followed the reading of the paper Dr. John McCrae of Philadelphia referred to its association with measles, and said that one man associated it with measles and another stated that he had never seen the disease in association. He suggested that milk might be a source of infection because hemolytic streptococci had been found in milk. It had been suggested by Rosenan that cheese might be an agency in conveying infection. MacCallum had had butter and cheese examined with the result that no streptococci had been found. In answer to a question by Dr. McPhedran as to the possibility of establishing immunity, the speaker said that efforts had been made in this direction in South Africa and had not been a complete success because the proper strains had not been used. Experiments made at Camp Upton seemed to indicate the establishment of immunity and held out the chief hope of preventing the dis-

ease. It was conceivable that an antitoxin might be produced but, in his opinion, the greatest hope lay in a vaccine. Probably a satisfactory degree of immunity would be produced, but intense work was needed to bring this about. MacCallum again referred to the futility of using vaccine when the epidemic was on the wane. It should be applied in the autumn when the recruits were coming into winter quarters. He believed firmly that the disease was spread by personal contact, for infection increased when men were huddled together in barracks. The disease commenced at Camp Dodge among negroes, and the greater number of cases among white men occurred in the barracks adjacent to the negroes. Concentration of men and personal contact were the main causes of the spread of interstitial bronchial pneumonia.

Army Death Rate Decreases.—An announcement from Washington, under date of June 13, states that the health conditions in army camps and cantonments continue satisfactory. A slight increase in the number of cases of pneumonia and meningitis is noted, with a decrease in measles, scarlet fever, and dysentery. Deaths for the week numbered 94, against 113 for the preceding week.

New American Red Cross Hospitals in France.—On May 30 two new Red Cross hospitals were opened in France. One, known as No. 5, had 200 patients on its opening day and at the time of writing had 600, which was the limit of its capacity. The other has 350 beds and all the Americans in a certain sector will pass through it on the way to American base hospitals. The Red Cross has now more than twenty hospitals in France.

Hospital for Our Navy in London.—Mrs. Edward Frederick Guest, the wife of one of the members of the British Parliament, has turned over to the American Red Cross her residence in Park Lane, known as Alford House, to be used as a hospital for the men of the United States Navy. Mrs. Guest was formerly Miss Amy Phipps of Pittsburgh.

New Military Hospitals in New York.—The War Department has taken over the ten-story building at the northwest corner of Lexington Avenue and Twenty-second Street, just completed by the city for the Manhattan Trade School for Girls, to be used as a war hospital. The building has a large housing capacity, having been built at a cost of \$700,000. The New York Homeopathic and Flower Hospital has plans for converting the adjoining six-story factory building which it recently purchased, into a hospital for wounded soldiers. It is estimated that the changes in the building and the equipment will cost \$100,000, and that when completed accommodations will be provided for 300 soldiers. Ground was broken, on June 10, for the McDonough Hospital, at 18 West 133rd Street, which will be used exclusively for negro troops. It will be a regulation hospital and contain 200 beds. Dr. Charles N. Dowd of the Roosevelt Hospital will head the surgical department. Dr. Howard C. Taylor and Dr. William Healy will be on the staff temporarily. All the nurses will be negroes.

Reopen Summer Home for War Hospital.—Mrs. Katherine Flower Kip of South Orange has opened her summer home at Leek Island, Canada, as a

hospital for returned wounded soldiers of the Dominion. Dr. Medford Runyon of South Orange will continue as head surgeon.

Expenditures on Army Hospitals.—A report from Washington shows that during the past six months \$25,173,417 has been spent by the Government on additions and improvements to the various hospitals of the army. Five hundred bed additions have been built to the hospitals of Camp Dodge and Camp Gordon at a cost of \$550,000. Additional two-story ward convalescent barracks are being provided at National Army and National Guard base hospitals, adding from 300 to 900 beds to each hospital. The total estimated cost of this construction is \$9,179,000. At each National Army cantonment two regimental infirmaries have been erected at an estimated cost of \$334,000. A dental infirmary operating building has been erected at each of the National Guard and National Army cantonments. Eye, ear, nose, and throat clinics have also been erected at each cantonment at a total cost of \$139,000. An additional 1,500 bed-hospital is now nearing completion at Camp Merritt, which will cost \$1,115,000. The engineer's training camp at Belvoir, Va., will soon have a 500-bed hospital, costing \$1,125,000. Construction in progress at the United States Army General Hospitals includes the following: Additional buildings at the Walter Reed Memorial Hospital at Washington, to cost \$773,400; a 1,000-bed tuberculosis hospital at Denver, Col., costing \$1,720,000; a 1,000-bed tuberculosis hospital at Azalea, N. C., costing approximately \$1,325,000; a 120-bed hospital at the Norfolk Quartermaster Terminal, costing \$205,000; a 1,500-bed hospital has been erected at Colonia, N. J., costing approximately \$1,612,000. At the United States General Hospital No. 6, at Fort McPherson, Ga., additional two-story quarters for nurses, accommodating 150, are being erected at a cost of \$88,700. A hospital for the care and education of blind soldiers is being erected at Hospital No. 7, at Roland Park, Md. A new tuberculosis hospital is under construction at Otisville, N. Y., which will accommodate 650 patients and which will cost approximately \$957,000. The Hospital at Fox Hills, N. Y., which is nearing completion, will accommodate 1,762 patients. At General Hospital, No. 14, at Fort Oglethorpe, Ga., two-story convalescent barracks are being erected which will give additional accommodation for 1,000 men. Nurses' quarters are in process of construction at all the army camps which will cost approximately \$1,000,000. This does not include all of the hospital construction work that is under way.

Dr. Henry Keller of New York has sailed for the Orient with the Palestine Medical Unit.

Austrian Red Cross Nurses Unfed.—Red Cross nurses attached to the hospital at Kirchendorff have informed the Austrian military authorities that the hospital will be closed unless the nurses are given adequate food, according to reports printed in Austrian newspapers and forwarded from Amsterdam by the Exchange Telegraph Company. The nurses, it is added, have been obliged to steal the rations intended for their patients in order to live. Some of them were caught and imprisoned for their thefts. The military authorities have promised relief.

New York, June 22, 1918.

ETIOLOGY OF SCARLET FEVER.

FROM time to time articles appear in medical literature on the etiology of scarlet fever, our knowledge of which has not been materially advanced in two decades. Owing to the widespread distribution of the disease and the frequently severe complications which accompany it, scarlet fever has been the object of extensive investigation by many eminent authorities, but very little information has accrued in regard to the exact nature of the *materies morbi*. Up to the present time no specific bacterium or demonstrable virus has been isolated which will satisfy all of Koch's original postulates. Early researches in this direction soon brought to light the fact that the streptococcus was an organism found with remarkable constancy in the throats of those afflicted with the infection. This soon led to the belief that some form of streptococcus was the actual cause, an idea that gained some measure of support when this organism was found in the blood stream of malignant scarlet fever cases. Subsequent work proved, however, that the streptococcus *per se* is not the inciting factor, but it does play an important role in the production of complicating conditions such as otitis media, swollen glands, heart and kidney involvement and other lesions of an acute inflammatory character. The streptococci isolated from scarlatinal anginas are not different from those obtained from many other sources, so far as cultural and morphological peculiarities are concerned.

In 1904 Mallory discovered in the skin of individuals dying from scarlet fever a rosette-like body which he was inclined to regard as protozoan in nature. Duval working along the same lines was able to find similar bodies in five cases which he examined. Since this time no adequate explanation of the significance of these bodies has been given. Two years ago Mallory and Medlar described a bacillus which they found in the bronchial mucosa, crypts of the tonsils, and on the soft palate, and to which they gave the name of *Bacillus scarlatinæ*. They were also able to culture from the tonsils and throats of scarlet fever patients a bacillus morphologically resembling the one they found in post-mortem material. Their description of the organism suggests a resemblance to the diphtheroid group of bacilli.

As yet no work has appeared establishing the etiological relation of such an organism to the disease. The great obstacle encountered is the production of the human homologue in animals.

Recently the subject was revived by Pryer and Kelly (*Jour. Lab. and Clin. Medicine*, Feb., 1918) who became interested in the problem from the standpoint of blood bacteriology. Once more the diphtheroid bacillus is incriminated, for the authors state that they were able to isolate from the blood a bacillus belonging to this heterogeneous group, in 79 per cent. of the cases of scarlet fever studied by them. What is more illuminating is the fact that they obtained presumably the same organism from the blood in one case of measles, two cases of diphtheria, and in six normal persons whom they used as controls. This bacillus was found to be non-pathogenic for the usual laboratory animals. In one fatal case of scarlatina, a coccobacillus was obtained from the blood, which possessed weak pathogenic powers, killing mice after four days. The authors are shrewd enough not to claim to have discovered the cause of the disease in this protean bacterium. It is evident that the status and distribution of the diphtheroid group are not definitely settled. By some workers these bacilli are regarded as saprophytic in their biological relationship to human tissues; by others they are considered as rank contaminations and of no pathological significance. In this connection one is reminded of the canard that was foisted upon an unsuspecting medical public a few years ago when it was announced that tubercle bacilli could be found in the blood of a large percentage of individuals infected with tuberculosis. An attitude of scientific scepticism should be adopted nowadays toward any organism purporting to be the specific cause of a disease of obscure etiology unless it will stand the acid test. In view of what we already know of the biology of the diphtheroid bacilli it would seem highly improbable that any member of the group could be the etiological agent of scarlet fever. It may be possible in the near future to place the infection among those caused by filterable viruses. At any rate this phase of the problem has not been so assiduously cultivated as the more tangible domain of pure bacteriology.

EVOLUTION OF OUR KNOWLEDGE OF VERRUGA PERUANA.

DR. ARCE, professor of tropical diseases in the University of Lima, writes on this theme in the *Anales de la Facultad de Medicina*, for January-February: The epidemic which attacked Pizarro and his followers is no longer believed to have been the disease in question despite a few points of similarity. The best evidence in favor of dualism is the silence of all records on verruga peruana up to 1764, when Bueno first alludes to it as a local malady "not always benign." In 1815 Unanue, the founder of the medical school in Lima, gave a short account of "las berugan" as a malady epidemic in certain regions of

Peru. In 1845 Tschudi, the traveler, termed it a fatal malady believed to be due, like goiter, to the use of certain mountain springs. So far it was evident that two separate clinical entities, benign and malignant, were known by a common name. In 1852, a student, Malo, wrote his thesis on the subject. It was an excellent first hand study. The author had never seen an example of contagion and showed that the disease could end in recovery or death.

Articles appeared at somewhat long intervals on the cause and nature of the disease concerning which numerous opinions obtained. In 1870 the construction of a railway from Lima to Oroya was responsible for an epidemic incidence and diffusion of the disease to new localities, and thus "Oroya fever" came into use as a designation, and the identity with the epidemic verrugas was lost for the time. Foreigners seem to have been attacked for the first time and the mortality was high, hundreds dying monthly. A commission appointed by the Government reported that a pernicious form of malaria was largely at the bottom of the epidemic despite its eruptive manifestations. Individual qualified observers insisted that the epidemic was one of verrugas. There is no doubt that Oroya fever possessed analogies with both pernicious malaria and the eruptive disease, verrugas, and a common cause was evoked for two maladies of widely differing clinical manifestations.

The situation remained confused until 1885 when Carrion, a medical student hero, inoculated himself with the discharge from a lesion of verrugas, and proved that the disease was identical with Oroya fever by dying of the latter in 18 days after the inoculation. Ten years before Pancoros had upheld the inoculability and identity of the two diseases, but without proofs.

In 1889 Patron advanced the view that the epidemic of verrugas which attacked Pizarro's band was Oroya fever, but the arguments were not convincing even if somewhat plausible. In 1899 Tamayo succeeded in transmitting the disease from man to the dog and in the same year Hercelles attributed transmission to the human race to mosquito carriers. Opinions as to the actual germ and the histological status of the specific lesions differed notably. The association of a granulomatous or neoplastic process with a special blood state was noted. Anemia was characteristic of the disease.

A vast amount of work now appeared on the subject from savants of all countries interested in tropical medicine. As a result the mosquito carrier theory seems to have been proven, but the alleged parasitic causes—notably the *Bartonella*—have not been fully shown to be such. The identity of benign endemic eruptive verrugas with Oroya fever has been firmly upheld.

MOBILIZATION PSYCHOSES IN THE SWISS ARMY.

UHLMAN refers to the well-known fact that at the outbreak of a war there is a general alteration in

the psyche of the entire community and an increase of psychic morbidity in both the military and civilian population. A contingent of psychoses also follows mobilization of an army even in peace times. The Swiss troops were mobilized at the outbreak of the present war and the author by communicating with the heads of the insane asylums obtained data as to the number of psychoses during and for several months following mobilization which were the direct result of the latter. There is of course no one cause for war psychoses but the content tends to have a military coloring and the type of the mental alteration is severe. Fear effects are common—a man fears that he will be thought a spy or traitor or deserter and expects to be shot.

In the first ten days of August about 250,000 troops were called out and 32 were evacuated to insane asylums. From August 1 to December 31 the total number of such evacuations was 151. In other words, the reaction due to mobilization was soon followed by equilibrium. Monthly figures show a steady decline and a curve for the five months' period shows a sharp rise which culminates August 10 and is followed by a short sudden and a long gradual fall. Among the mobilization psychoses those due to alcohol are always well represented and of the 151 cases 35 were of this origin. The proportion is especially high in the older men of the landwehr and landsturm—12 cases out of 39. The proportion of alcohol psychoses in the marching troops was 20 per cent. It would, however, be unfair to regard all such cases as examples of delirium tremens for subjects with endogenous psychoses may drink to excess. It is almost certain that some of these cases should be credited to dementia precox. All of these alcohol psychoses were chronic. The author has no single classification of dementia precox and follows the asylum diagnoses, which evidently are not patterned throughout on Kraepelin's classification. We find 61 cases of dementia variously termed katonie, hallucinatory, paranoid, and hebephrenic, which doubtless jointly answer to dementia precox, and adding the 35 alcoholics obtain a figure that represents two-thirds of all the mobilization psychoses. Others are as follows: Manic depressive insanity, 7; melancholia, 3; exhaustion psychoses, 2; paranoia, 1; progressive paresis, 1. In addition to psychoses proper there were 8 imbeciles and a number of psychopathic and psychoneurotic subjects, comprising 16 with the simple diagnosis of psychopathy, 8 cases of hysteria exclusive of 2 somnambulists and 6 epileptics. There were 2 deaths exclusive of suicides. There were from 25 to 30 suicides during the five months' period but the relationship of insanity is not made clear. In about a third of the 151 cases there was an hereditary taint.

GLANDERS IN THE WILD FELIDÆ.

OF more than veterinary interest is the alleged incidence of disease due to the *Bacillus mallei* in captive lions and tigers, as well as in the domestic cat. An article on this subject is contributed by Carpano

to the *Annali d'Igiene* for February 28. The author, a veterinary pathologist received for examination last June a piece of lung tissue from the body of a tiger which had just died in the Rome Zoological Garden. The illness had been very brief, the only symptom having been anorexia, constipation, and extreme prostration. The author readily isolated from the specimen a germ known to cause hemorrhagic sepsis. A lioness in the same zoo which had been seriously ill for five days was found to have a superficial lesion a biopsy of which revealed the existence of acute glanders complicated with a pasteurellosis. Cases of glanders in lions, tigers, and leopards are by no means unknown and the disease is known to have been transmitted from the horse to the lion. Melvin in the United States has recently recognized by serodiagnosis a case in a lion belonging to a traveling menagerie. The animal presented ulcers in the nose and on the face, back, legs and feet. Twelve other lions had previously suffered from the disease. The felidæ in general, including the domestic cat, are evidently very susceptible to this contagion and laboratory cats have often been successfully inoculated. The epidemic in the Roman Zoo was traced back to 1912. The first victims were a twin lion and lioness, the parents of which were from Abyssinia. The lioness succumbed and the lion was placed in a cage with two other females and later in a separate compartment where he fell ill. At the same time a tiger and tigress fell ill and all three animals died. The infection also spread to the lionesses already exposed and then seemed to have been extinguished. The pathological report is unfinished but the author announces in the opening paragraphs that the infection was at least in part a mixed one of *Bacillus mallei* and the *B. felisepticus*.

EPIDEMIOLOGY OF 1917.

FROM a partial report in the *Office International d'Hygiène Publique* for February it appears that cholera has prevailed since January 1, 1917, in British India, the Dutch East Indies, Indo-China, Siam, the Straits Settlements, Asiatic Turkey, and the Philippines; bubonic plague in Brazil, Peru, Ceylon, China, British India, the Dutch East Indies, Indo-China, Siam, the Straits Settlements, Hawaii, and New Caledonia; and yellow fever in the Belgian Congo, Dahomey, Nigeria, Brazil, Ecuador, Mexico, and Venezuela. Quite recently the plague has also appeared in Egypt and Senegal. The chief morbidity from cholera was in Bengal, Assam, and the United Provinces, with 55,000 deaths, while in the Philippines there were 8,770 cases with 5,587 deaths. There were also many deaths in the Punjab and Burmah. In no other localities were four figures reached. The morbidity from plague was also highest in British India, reaching 590,000 cases, with 362,000 deaths. The largest contingents came from Bombay and Sind, the United Provinces, the Central Provinces, Hyderabad, and Rajputana, in which areas the figures ranged from 147,000 to 28,000. There were also many in Madras, Mysore, and Central India. There were 64 deaths in Brazil, and several hundred cases in Peru. There was but a single case reported in Hawaii. The entire morbidity of yellow fever did not exceed 150 cases, of which over half occurred in Guayaquil, in Ecuador.

News of the Week.

Epidemic in Spain Passing.—The epidemic of mysterious disease resembling grippe which recently swept over Spain is steadily subsiding, according to a recent dispatch.

Smallpox in Germany.—A recent report from The Hague quotes a neutral who has arrived there from Germany as stating that an epidemic of black smallpox is raging among the workmen of the Krupp plant at Essen with four or five fatal cases occurring daily.

Funds Needed to Care for Paralysis Patients.—The New York Committee for the After Care of Infantile Paralysis is making an appeal for \$100,000 with which to continue its work during the year 1918. The Rockefeller Foundation some time ago contributed \$41,000 toward this fund and now announces that it will give an additional \$16,000 toward the executive expenses of the committee, exclusive of treatment, transportation, and the purchase of braces. Since the epidemic of 1916 the committee has cared for 8,013 cases and 1,992 have been reported as cured. There are 4,897 cases still under treatment.

Milk for Babies and Soldiers.—Nathan Straus has planned to open five additional milk stations where milk will be sold for infants at a nominal cost and given free to soldiers.

Malnutrition in Babies.—On one day recently at the New York Diet Kitchen Association, of 66 babies examined 50 per cent. were found to be suffering from malnutrition and at least 50 per cent. had enlarged tonsils and adenoids. To remedy the conditions found at the various examination centers a house-to-house canvass of the 600,000 children under five years of age in New York City is to be undertaken. When abnormalities are found the parents will be directed with reference to having them remedied.

New York Clinic for Speech Defects.—Though only opened a few months ago, the New York Clinic for Speech Defects already has an active service embracing over 300 cases. This is the first free medical clinic to be licensed by the State Board of Charities devoted solely to the cure of defective voice and speech conditions. The clinic has as its object the cure of all forms of speech and voice disorders and the care of defective teeth, mouth or jaw conditions when such conditions are a causative factor of defective speech. It also takes care of nervous and mental conditions when such conditions are causative or associated with defective speech. In addition to the clinical work, a Central Bureau of Information is maintained which serves as a clearing house for speech and voice disorders.

Dr. Pozzi Killed.—Dr. Samuel Pozzi, the well known surgeon of Paris, was shot and killed on Thursday of last week by a former patient. The man had been operated upon by Pozzi last winter and complained that the operation had not cured him. After killing the surgeon the assassin shot himself.

James E. McBride, president of the Municipal Civil Service Commission, who was recently active in the prosecution of the abortive campaign against the Health Department initiated by Mayor

Hylan, has resigned his position in the Civil Service Commission.

Instruction in Health Work for Volunteer Workers.—In cooperation with the People's Institute, the Federation for Child Study, and the Bellevue Social Service, a course in war time training for volunteers in health work for children of school age is being conducted by Teachers' College under the auspices of the Nutritional Committee.

Hospitals Lose Bequests.—The Syracuse Hospital and the House of Rest for Consumptives will each lose a bequest of \$5,000 and the New York Association for the Blind will lose \$10,000 bequeathed by the will of Mrs. Mary Elizabeth Turnure, because the will was not admitted to probate, owing to the fact that the testator was said to be incapable of making a will at the time, the signature was said to be illegible, and the witnesses, it was believed, were not present at the time of the signature.

Society Elections.—THE FRANKLIN COUNTY MEDICAL SOCIETY (VT.), at its meeting in St. Albans, on May 29, elected the following officers: *President*, Dr. H. L. Pierce; *Vice-President*, Dr. A. O. Marton; *Secretary-Treasurer*, Dr. E. A. Hyatt.

THE FLORIDA STATE MEDICAL ASSOCIATION, at its annual meeting at Miami, on May 20, elected the following officers: *President*, Dr. F. J. Walters of Daytona; *First Vice-President*, Dr. W. P. Adamson of Tampa; *Second Vice-President*, Dr. E. Mason Smith of Chattahoochee; *Third Vice-President*, Dr. W. H. Coffee of Winter Haven; *Secretary-Treasurer*, Dr. W. R. Warren of Key West.

Obituary Notes.—Dr. JOHN MERRITT, a graduate of the Long Island Medical College and Hospital, in 1875, died at his home in Brooklyn on June 9, aged 72 years.

Dr. ERNEST V. SCRIBNER died at the Worcester State Hospital, Massachusetts, of which he had been superintendent six years, on June 14, aged 63 years. He was graduated from Bowdoin College Medical School in 1881, and was connected with the work of the Grafton and Worcester State Hospitals for many years.

Dr. STEPHEN W. GERROW, a graduate of the Castleton Medical College, in 1856, died at his home in New Paltz, N. Y., on June 10, aged 83 years.

Correspondence.

WARBURG'S TINCTURE IN MALARIA.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Dr. Beverley Robinson recently took occasion in your columns to extol the efficacy of Warburg's tincture in the treatment of malaria. His article has prompted Dr. H. Rabinowitsch to reply that its therapeutic value is due entirely to the quinine which it contains. This assertion is quite erroneous, for we all know that the proportion of quinine contained in the preparation—about one grain to each fluid dram—is far short of sufficient by itself to effect the desired result.

Experience has taught us that it is not so much the quinine as the manner of its combination with the various stomachics and carminatives that make Warburg's tincture a powerful antimalarial agent.

In the realm of therapeutics you will find a number of instances of a drug's potency being increased by properly combining it with others. For instance, a large dose of calomel is not nearly so good a purgative as a small dose triturated with bicarbonate of soda. I have always found Warburg's tincture, with its little quinine and with much of other ingredients, to be an unfailing specific for all stubborn malarial conditions.

MORRIS ZUCKER, M.D.

706 SIXTH STREET, NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

MEDICAL PRACTITIONERS AND THE ARMY RESERVE—BRITISH DELEGATES TO THE AMERICAN MEDICAL MEETINGS—TREATMENT OF WAR NEUROSES—THE PRIMARY EXAMINATION FOR THE FELLOWSHIP OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND—THE DISABLED SOLDIER AND SAILOR.

LONDON, May 24, 1918.

THE Military Service Acts of various dates in 1916, 1917 and 1918 made various calls upon and some concessions to members of the medical profession of military age, and Sir Auckland Geddes, the Director General of National Service, has now issued definite directions regulating the whole position. It was time that some such public announcement was made, for many medical men had ceased, in the kaleidoscope of official pronouncements, to recognize their place in the pattern. Sir Auckland Geddes' memorandum states that every duly qualified medical practitioner who was born after April, 1862, and who is a reservist, either by virtue of the Military Service Acts [1916-1918] or by an act of voluntary attestation, must report himself for medical examination on receipt of the usual notice in use under the Reserve Forces Acts. Such a report being required by the ministry and delivered by the doctor, the doctor will be under the usual penalties to join the colors under a calling-up notice, but need do nothing until such notice is received. The interesting point for medical practitioners of military age who are reservists—and practically all of them by this time belong to the Army Reserve, either by presumption or enlistment under one act, or by transference under another, or by voluntary attestation—is that they will receive individual notice to present themselves for medical examination. This regulation shows that it is intended to exercise care and discretion in the use of the now distinctly attenuated line of medical defense, and may be taken as an indication of the value of having, where medical matters are in question, a person in authority who has a practical knowledge of the medical profession. It must be remembered that Sir Auckland Geddes is a medical man, Professor of Anatomy in McGill University, Montreal, and lately assistant professor in the same subject in the University of Edinburgh. He is, therefore, considerably familiar with all the problems of medical life, and knows that in many cases doctors of equal age, attainment, and physique, may be very unequally placed as far as professional circumstances count. Under the new regulations no practitioner need present himself for medical examination until he receives his notice, and no practitioner will be called up until he has received a further notice from the Bureau of National Service,

giving information how to apply for any certificate of exemption which he may desire to obtain.

Sir James Mackenzie, the well-known heart specialist, Sir W. Arbuthnot Lane, and Colonel Henry Bruce of the Canadian Army Medical Corps, representing very aptly scientific medicine, progressive surgery, and medical administration, have left for New York as the British delegates to the American Medical Conferences. American leaders of medical thought will find them as ready to absorb information as to impart it, and that is a good quality for a delegate to possess.

The treatment of sailors and soldiers suffering from war neuroses, shell shock, alleged shell shock, and the allied conditions, is becoming a matter of increasing importance, and it is good to see that this fact is being recognized by naval, military, and civil authorities in the right manner. How serious the position would be if precautions were not taken to mitigate it is intimated by the estimate that of the whole of the unwounded soldiers discharged from the army one-third fall under the heading of functional neurosis. Now undoubtedly this mass of men are suffering from conditions whose result can be cured by suitable treatment, but only if the treatment is based on correct diagnosis and is administered at a fairly early date in the pathological condition. "Hysteria," using the word as conveniently inclusive, and not as strictly scientific, if treated promptly, can be readily eradicated, but the diagnosis calls for great care. If to be fooled by a pretender or a semi-pretender is a reproach to a medical man, it must be remembered that to class as an impostor a genuine sufferer is a far greater reproach. At the present moment a large number of discharged soldiers and some discharged sailors are receiving pensions, while their different palsies and contractures were undoubtedly hysterical at the commencement, and Dr. Christopher Addison, the Minister of Reconstruction, has inaugurated a movement to prevent this wrongful expenditure of public money. Here again we see the importance of having as a responsible minister one who is acquainted with the ordinary problems of professional life when medical affairs are on the tapis, for Dr. Addison, like Sir Auckland Geddes, was until recently attached to the teaching department of a large medical school. As head of the anatomy department of St. Bartholomew's Hospital, Dr. Addison was in touch with things medical for many years, and the knowledge thus gained has been exemplified in his attitude toward the medical profession throughout the stress of war. The step which is now being taken by the Minister of Reconstruction to obviate the abuse caused by regarding the functional disabilities of crowds of men as incurable has been to lay down a method of instruction for doctors, whether serving in the army, or civilians, by which they may recognize among the patients who come before them those who are suffering from uncured neurosis or neurotic relapses brought on by emotional worry. It is inevitable that this war, long-lasting, and attended with every circumstance that is calculated to try the nervous stability of all classes, should leave for a considerable time a widespread emotivity in the population. This is the sort of feeling which alike flourishes under undeserving sympathy and is inspired by the idea of a

life pension. It has now been decided by Dr. Addison, who has been in communication on the subject with Surgeon-General Goodwin, Director General of the Army Medical Service, to institute at the Maudsley Hospital a course of instruction to a limited number of medical men, civilian as well as military. The plan of the course has been laid down; it consists of lectures and practical instruction in the causation, diagnosis, prognosis and treatment of all the functional conditions of the nervous system which have so far come under medical and surgical supervision as being attributable to the war or war conditions, and the whole curriculum will be under the direction of Colonel F. W. Mott, who finds himself established, without effort and without challenge, and, since the beginning of the war, in the position of the leading neurologist of the country. It is a coincidence that the will of the late Dr. Henry Maudsley should have been proved this week, for in that will is registered his munificent donation of £10,000 toward the foundation of a hospital for the treatment of mental disease; that is to say, of the very institution where war neurosis is now to be considered scientifically.

Sir William Osler is definitely recognized in England as the most broadminded authority on medical education whom the country possesses. He appeals to the judgment of his profession, here and abroad, in a double capacity. If the academic side of medicine is considered, what can be more academic, what, indeed, more picturesquely medieval, than to hold one of the four great and ancient chairs in the University of Oxford? If the practical side of the medical profession is in question, Sir William Osler's work, first at the McGill University, and later, with added importance at the Johns Hopkins University, acclaims him as progressive in the best sense of the word. It is generally felt that when he advocates a departure he does so in the belief that along the course which he indicates the wisdom of the past can be best applied to the needs of the present and to the promise of the future. Therefore when Sir William Osler speaks he receives attention. He has lately published in the columns of *The Lancet* an open letter to the president of the Royal College of Surgeons of England calling attention to the fact that the figures just published in the journal with regard to the Primary Examination for the Fellowship of the College present much food for reflection. The figures showed that out of thirty-four candidates for the pass twenty-seven had been rejected, and Sir William Osler maintains that the system of examination must be at fault when such wholesale destruction is dealt out to what are presumably the pick of the medical schools. Surgeon-General Sir George Makins, the president of the college, has replied, acknowledging that experience of the result of the Primary Examination for the Fellowship had been for some time a source of grave concern alike to the council which manages the affairs of the College and the Board of Examiners who are themselves immediately responsible for the wholesale rejections. But Sir George Makins, senior surgeon to St. Thomas' Hospital, to which institution there is affiliated a very sound medical school, makes a shrewd point when he indicates that the institution of special

classes at the various medical schools for those students who intend to compete for the Fellowship had contributed to the fact that more unfit students nowadays than heretofore were presenting themselves for these honor examinations. For "horror" examinations those for the English Fellowship undoubtedly are, though conducted on "pass" principles. The implication is that while the examiners try to broaden the issues and to discover by their questions whether the candidate is, generally speaking, sufficiently well equipped to receive a diploma which has a very high standing, the teachers in the special classes are pinning the attention of their particular students down to details which may or may not be required of them in the course of the examination. This means that if the examination runs along the same lines as those traversed by the coach the candidate will probably get through, but if the examination departs from those lines he will probably be rejected. Sir George Makins does not say or even imply this, but that is the situation which arises definitely out of his suggestion that the "Fellowship class at medical schools is responsible for the perplexing figures over which discussion has been aroused," and many medical schools, when medical education is in the reshaping, may take this hint to heart. Sir Henry Morris, a late President of the College, who, as representative of the Corporation on the General Medical Council, made many forceful contributions to educational debates, evidently believes that far more of the blame attaches to the students than either to the system of examination or to the teachers. He suggests that a large percentage of the candidates for the First Fellowship are senior men, not working under the eye of any teacher attached to a medical school, but entering for the examination, having received the necessary certificates of attendance, at their own will and on their own responsibility. This forms a third class of candidates, as such men are of course not undergoing the ordinary instruction of any school, and are not suffering from the meticulous and disturbing instructions of a Fellowship class, and it is obvious that Sir William Osler has started an investigation that may be of considerable practical value in respect of a really complicated situation. In one direction investigation will be difficult, and yet it is a direction in which it might be fruitful. The value of passing the Primary Fellowship Examination of the Royal College of Surgeons of England is very great to a young man. Without the primary examination he cannot, of course, go in for the final examination, and without possessing the diploma of Fellow some of the higher avenues in pure surgical work will be closed to him. The temptation, therefore, to "take a shot" is very strong. In every examination the element of chance enters. Professor Edgeworth of Oxford, using the figures and replies of a difficult examination for posts in the British Civil Service as his material, has made the following deductions. Of a given number of candidates there will always be a percentage who, in the absence of momentary aberration, cannot fail; and a percentage who in the absence of phenomenal good luck cannot pass; and, somewhere between these extremes, there will be a

number of candidates so near the just acceptable line that those of them who had failed, on being re-examined immediately, would pass, and *vice versa*, those of them who had passed, on re-examination would fail. Professor Edgeworth's views have never been disputed, and the probability is that a good number of candidates for the Primary Fellowship of the Royal College of Surgeons of England enter themselves for the test on what they would call a sporting chance. Such candidates do not deserve any more sympathy than does the gambler who puts his money on an outsider; in either case if they win they cannot suggest that they have deserved their fortune; nor can they allot any blame if they lose.

The second Inter-Allied Conference on the Care of Disabled Sailors and Soldiers was opened this week by the Duke of Connaught. For the delegates Dr. Bourrillon, President of the French Committee for the care of the disabled ex-service man, spoke with great eloquence, being supported by Lieutenant-General Mélis, who represented Belgium, and Prof. Enrico Burci, who represented Italy. A well arranged and instructive exhibition in connection with the Conference was also declared open by the Duke of Connaught. The aim of the exhibition is to illustrate the work done at various military hospitals in France, Italy, Belgium, Serbia, Great Britain and her dependencies, in order to educate the sailors and soldiers whom the war has thrown back on their respective states in various plights of disablement. The problems presented and their methods of solution deserve the attention of all the allied belligerent states.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

AIR RAIDS—RED CROSS FEEDING THE SCHOOL CHILDREN —THE FRONT LINE CANTEN

PARIS, May 8, 1918.

THE Germans are believed to have organized to bombard Paris from the air systematically and they gave us a sample of what they could do twice during the first week in March and many times since. The Paris government has built concrete walls and piled sandbags about the most prominent of the public monuments and particularly those of marble figures, impossible to restore or replace. The American Red Cross has established fixed stations and assigned ambulances which proceed to their stations at the first alarm and remain to hunt out and care for the wounded during the continuance of all raids and are rendering a service which is highly appreciated by the Government. Our men are alert, willing, and fearless and not only here but everywhere are holding to the best traditions. During a prolonged and destructive air raid (the worst since October 17 last) the men of the A. R. C. Transport Service at Nancy were able to render efficient assistance in picking up the wounded, going out soon after the first bombs fell early in the evening and continuing the work until 2 a. m.

Another item worthy of special note concerns Lieutenant William H. Sperry of the Civil Affairs Department. He, with five American soldiers, went to the freight yard and while the bombard-

ment continued they moved more than eighty cars away from the raging fire and thereby saved no end of merchandise. They moved the cars both by hand and with an engine they found deserted and which one of their number was able to run. The French authorities are very appreciative of this voluntary and prompt assistance on the part of our men. The soldiers who assisted Sperry were Corporal Thomas G. Henderson, Eugene Hufeld, Harry Tomas, Jack Campbell, and Robert Nesbitt.

Twenty-one hundred poor, under-nourished school children of the Fourteenth arrondissement of Paris, received Friday afternoon their first taste of American Red Cross food in the shape of a scientifically prepared sweetened roll made of wheat flour and rice and a bar of chocolate, replacing the 4 o'clock "goûter," discontinued since the war. Every day the "goûter" will carry a message of allied friendship and the work of supplementing the food in the school canteens will be extended to the most needy districts of the city.

Throughout Paris the Children's Bureau of the American Red Cross has established free dispensaries for the medical care of the poor children of the districts; in these clinics it was found that the children were not so much ill as badly nourished—they were not underfed, but they were not being fed the proper kind of food. The children have been forced since the war to take more and more meals outside the home because their mothers, obliged to become wage-earners for the family, cannot give their accustomed time and attention to the household. The children naturally turned to the canteens of the schools. Upon investigation it was found that the menus in these canteens, although not greatly changed since the war, were considerably decreased in quantity, and the diet—wholly insufficient—no flour, little milk, and no sugar. It is these foods, so necessary to the nourishment of the child, that the Red Cross is aiming to provide.

The first distribution of the Red Cross contribution in the Fourteenth Arrondissement was attended by much ceremony. A delegation from the Children's Bureau was conducted by M. Ferdinand Brunot, mayor of the district, the well-known philologist of the Sorbonne, to the different schools of the arrondissement, where the ladies of the delegation distributed the "goûter." In each school the children trooped down to their assembly rooms and were addressed by Mr. Brunot, who explained most graciously the motive of the gift as an expression of Allied solidarity. He told the children what the American Red Cross was and explained to the tiny ones who had not been initiated into the mysteries of geography that the food came from people who lived "away, away off, on the other side of a great big sea." At the last school he made a brief speech in English of appreciation of the work of the American Red Cross. In every instance the assembly rooms were decorated, some more elaborately than others, but all with a nice feeling for the spirit of the American alliance and in each school a reception had been prepared for the American visitors. A group of little girls in one school sang "The Star Spangled Banner" in French transla-

tion with extraordinary ability, and at the same school two small standard bearers, one with the French colors, the other with the Stars and Stripes, made speeches of welcome and allegiance. In another school a large class of girls sang "The Star Spangled Banner" in excellent English; one of the pupils made a speech of appreciation also in English, and a large poster, designed, drawn, and colored by one of the pupils, which bore the words "Merci à la Croix-Rouge Américaine," was presented to the Children's Bureau.

A front line canteen service for American soldiers will be inaugurated by the American Red Cross this week. This morning two Red Cross workers will leave Paris to establish the first hot-drink station with the American troops on the fighting front. A point was selected a few days ago by the colonel and chief surgeon of the division of the American troops who are holding the trenches a few kilometers away. Naturally the point cannot be named, but the men who are going to work there know what they are in for. One of them has served six months in the Red Cross front service with the French troops and won an enviable record. The work done for the French had only one object in view—to aid the friend "poilu," but it happens that it was the best possible preparation now that the time has come to help our own boys in the trenches.

Hot drink station No. 1 for the American troops is placed at a central point behind the American artillery, within walking distance of the communicating trenches, within firing distance of the German guns, and within gas-mask distance of the German gas. It is the last point where the soldiers halt going into the trenches and the first coming out. Here, in a little kitchen tucked beneath unobtrusive walls of sandbags and cement, the Red Cross workers will serve steaming drinks to the mud-stained tired fighters. And at a telephoned word from the trenches big Norwegian heaters will be filled with hot bouillon, and two men carrying a heater on a pole will go forward past the artillery, through the communicating trenches into the front lines.

With the French the American Red Cross has had twenty-five such stations. Sometimes the workers lived in dug-outs, often they wore gas masks. One has a dented helmet which make clear how near he came to "going West." To the poilus more than a million hot rations have been served by the Red Cross front service. The work is hard and long and the hours ungodly. It is a splendid service for any man not in the army, a man with nerve, energy, and intelligence. There is no finer. All preparations have been made to add nine new front kitchens to Station No. 1, and as fast as they are called for and as fast as the kind of men needed for the work are obtained the service will grow. There is no longer any reason for a man who cannot get into the army to sigh for action. He can get all he wants in the Red Cross front line service.

Two Americans, Mr. Herbert M. Sears and Mr. J. S. Stevens, who have been working with the canteen service on the French front, have been recommended for decorations. Another American worker has been made an honorary Chasseur

by the members of that magnificent French fighting unit. Only American citizens who are over military age or otherwise unacceptable for the army, are eligible for the Rolling Canteen Service, as it has been named. The work, however, is not easy and is full of risk and danger. The conveyors are usually kept near the front line trenches and often within rifle fire distances. It is part of their daily work to go up into the first-line trenches and distribute soup, coffee, tea, and chocolate to the brave but mud-spattered and weary "poilus."

The work with the French and American armies is under the joint direction of Mr. Barrett Fithian of California and Mr. Sanford D. Pomeroy of New York. The work will be expanded within a short time and it is expected that a number of so-called hot-drink canteens will very soon be established at a number of different points on the American front.

1. Congenital Pyloric Stenosis.—W. E. Ladd advocates pylorotomy rather than the more formidable operation of gastro-enterostomy in cases of pyloric tumor. He believes that such tumors are congenital in origin and in support of this view refers to the finding by Dent and others of a pyloric tumor in the fetus. The indications for operation are: the typical story, the physical findings, loss of weight and failure to improve under medical treatment. In doubtful cases the x-ray will often settle the question. It is important of course that the medical treatment should not be continued until the baby becomes so weakened as to be a poor surgical risk. In performing the muscle-splitting operation, or pylorotomy, the muscle fibers must be thoroughly separated from the stomach to the duodenum, as otherwise a constriction will be left; and the mucous membrane must be allowed to come up to the level of the serous surface to avoid the muscle falling together again. At the duodenal end, care must be taken that the thin mucous membrane is not perforated. In true pyloric stenosis, the pylorus is hard, inelastic, and when cut scarcely bleeds at all, the cut surface being white and appearing almost like cartilage. In the milder type, which Ladd would classify as pylorospasm and in which the tumor is soft, elastic, and when cut bleeds freely, the muscular and mucous layers not separating easily, the muscle-splitting operation should not be done; indeed, Ladd believes that such cases should not be operated on at all. He sums up the result of his experience by saying that since adopting the muscle-splitting operation he has obtained a more definite picture of the characteristics of the pyloric tumor, which he believes to be congenital in origin. He recommends operation without delay in cases in which obstruction is nearly complete and considers that in doubtful cases the x-ray is valuable in deciding the advisability of operation. In his experience the use of the x-ray has been followed by no bad results. The mortality has been much lower following the operation of pylorotomy than that of gastroenterostomy, and for that reason he considers pylorotomy the operation of choice. He adds that he hopes that with less delay in operating on the cases that should be operated on, and not operating on those that should not be operated on, the results in future will be more gratifying than they have been during the last three years.

4. Acute Infectious Jaundice (Spirochetosis Icterohemorrhagica).—Charles Herrman believes that the so-called catarrhal jaundice, epidemic jaundice, Weil's disease or Spirochetosis icterohemorrhagica, probably represent a closely related group. Clinically they are similar, the difference in the majority of cases in each group lying solely in the degree of severity. Mild, moderate, and severe or fatal cases are met with in each group. He points out that the infectious material probably enters the body through the nasopharynx, is then taken up in the circulating blood, and has a selective affinity for the bile ducts of the liver. It is probably a primary infection of the liver, not an ascending infection from the duodenum. The disease, he believes, is not due to indiscretions in diet; nor is there any conclusive evidence that the infectious material is conveyed by food or water. One type of infectious jaundice, Weil's disease or Spirochetosis icterohemorrhagica, has been shown to be due to a specific spirochete and it is not unlikely that sporadic and epidemic jaundice of the so-called catarrhal type is due to a related organism. Herrman believes that infection usually takes place by direct contact but adds that it is not unlikely that, occasionally, the infection may occur indirectly, through infected urine or fecal matter. The disease is only slightly communicable, for apparently most individuals enjoy a natural immunity. One attack renders the patient immune to future attacks. In civil life, sporadic and epidemic jaundice is somewhat more common in children, probably because they are more susceptible and have not been immunized by a previous attack. In camps the disease is most common among recruits from rural districts, because a certain number of nonimmune or susceptible individuals are brought into close contact.

1. The Effect of Phosphorus on Growing Normal and Diseased Bones.—D. B. Phenister refers to the experimental work of Wegner and later observers on the effect of phosphorus on growing bones, and gives a number of roentgenographic studies of cases in which phosphorus was administered, with a description of the changes brought about by its use. He found that phosphorus affected the normal bones of children in much

the same way as described by Wegner in the case of experimental animals. The effects on enchondral bone growth were especially well marked. No definite increased transverse growth could be made out, but this, if slight, might easily escape detection by means of the roentgen ray. We noted that for some time after the use of phosphorus was stopped there was continued but less marked overproduction of bone in the juxta-epiphyseal region of the shaft, due probably either to the cumulative effect of the phosphorus or the stimulating influence of the excessive stores of calcium salts in the neighboring bone. The diseased bones showed certain variations. In osteogenesis imperfecta, the transverse growth was as strikingly affected as the longitudinal. All fractures occurring during the period of observation healed except one at the middle of the left humerus, which occurred during the period of interruption of phosphorus, an inactive stage of non-union being established before renewal of the drug. Phemister concludes that, if given early in fractures during the active period of repair, phosphorus should stimulate callus formation and ossification; in nonunion, however, when the natural reparative impulses have been exhausted, little should be expected from its use. Roentgen-ray studies of bones during the administration of the phosphorus show that, given alone, it has a marked stimulating effect on bone production and calcium accumulation in the normal zones of growth, and speak against the assertions of Schabad relative to calcium metabolism in healthy children. In the florid stage of rickets, however, phosphorus is unable to restore the power of depositing lime salts lost by the bony tissues and no appreciable effect from its administration would be detectable by the roentgen ray, although such administration may increase the amount of osteoid tissue formed. During the healing stage, phosphorus would stimulate the formation of osteoid tissue and consequently increase the amount of bony tissue formed. It must be remembered that during the healing stage of rickets, from the rapid ossification of osteoid tissue piled up in the metaphysis during the florid stage, a condition forms which roentgenologically resembles the phosphorus changes in normal bones, and that phosphorus administration would intensify this condition.

2. Tachycardia: Observations Upon Its Occurrence in the Enteric and Other Fevers.—Major H. Fairley Marris gives the results of observation of a large number of cases belonging to the enteric group of fevers, in which he has paid particular attention to the symptom tachycardia. In some cases the tachycardia developed gradually during convalescence, in others its onset was abrupt, and others again—the minority—were conspicuous by the presence of rapid heart action throughout the disease. The method of investigation adopted by Major Marris comprised observations by polygraphic records and the study of the cardiovascular mechanism and its response to various changes. He noted the effects of sleep on the disordered pulse-rate, the length of time for which respiration could be voluntarily suspended, and the effect of changes of posture, as well as the presence or absence of signs and symptoms of heart failure. On the basis of these observations he has divided the cases into four classes and he gives a short description of a typical case of each type. In case 1 the tachycardia was observed to arise in a permanently damaged heart and was therefore cardiac in origin. This case was one of true typhoid in which the following points were noticed: occurrence of valvular disease and

of necessity a damaged myocardium; rapid heart rate throughout illness; rapid pulse rate during sleep; breathlessness always present, the maximum period of voluntary arrest of respiration never exceeding 12 seconds, whereas in healthy controls the breath could be held for from 20 to 60 seconds. The second case was one of severe paratyphoid B, in which rapid heart action and respiration were observed for four weeks; a rate of 144 per minute alternated with a slower rate of 96 per minute. This type is described by Major Marris as "phasic." In the early stages the tachycardia was observed both in waking and sleeping states and the arrest of respiration was unduly curtailed. This case Major Marris regards as of toxic origin, due to poisoning of the heart muscle by toxins generated by the infection. As convalescence was established the heart rate both during waking and sleeping states and also in the erect posture was that seen in healthy hearts, the cardiovascular system having completely recovered. The third case, of moderately severe paratyphoid A, is described as one of vasomotor tachycardia, although Major Marris states that its interpretation is uncertain. In this type the tachycardia is not cardiac in origin, the sleeping pulse, the effects of posture, and the period of arrest of respiration all being normal. In the early stages there was some dilatation of the heart due to poisoning, but the tachycardia developed during convalescence, together with sweats, tremor, cold and clammy extremities with dermatographia. The fourth case, a moderately severe case of paratyphoid B, was characterized by considerable abdominal distension during acute stages. In the early days of the disease the heart showed evidence of dilatation similar to that in case 3. The tachycardia developed when the patient got up from bed for the first time but was relieved by the application of a tight abdominal bandage, the pulse rate falling from 150 to 120 per minute—and on resuming the recumbent position the rate fell to 90 per minute. The heart itself was normal in size, sound and rhythm and the pulse rate was always slow during sleep. This type Major Marris describes as the postural or atonic, induced by the temporary dilatation of the great abdominal veins. Marris finally classifies these cases into three groups, placing types 2 and 4 in the same group—the postural or atonic. These groups are—(1) those due to cardiac lesions; (2) postural or atonic cases; (3) those due to general instability of the vasomotor nervous system. Similar observations were carried out in other febrile disorders. In the fatal cases, such as diphtheria, scarlet fever, cerebrospinal meningitis, military tuberculosis, the tachycardia was of cardiac origin, the majority of non-fatal cases belonged to the vasomotor group, and a few of the postural variety were encountered in obscure febrile disorders. As to treatment, Major Marris recommends that the first class, those of cardiac origin, should be treated as heart cases; in the vasomotor group the patients should not be put to bed but given a gradually increasing amount of exercise and massage, and in such cases the use of ammonium bromide appeared to hasten convalescence; nor should cases of the postural or atonic type be confined to bed, tonics and massage should be given, and the application of an abdominal binder was found to be of benefit in some of them. Marris then adds a description of a few cases of the vasomotor variety of tachycardia which he observed during the first few weeks after inoculation against the enteric fevers, and from which he concluded that an emulsion of dead bacilli may give rise of vasomotor tachycardia. He points out that such cases should not be regarded too lightly or returned to duty entailing arduous and sustained effort until the vasomotor mechanism has had time to regain its normal tone.

1. **The Prophylactic Use of Quinine in Malaria, with Special Reference to Experiences in Macedonia.**—Captain C. H. Threadgold discusses the prevalence of malarial infection in Macedonia, both among the French and British troops, and considers the effect of the administration of prophylactic quinine both in the prevention of illness and on the general course of the disease. He shows that, other things being equal, the natives of malarial districts derive more benefit from quinine prophylaxis than do immigrants from non-malarial countries. From a study of available statistics it appears that some of the men who were exposed to infection in Macedonia escaped because they were never bitten by infected mosquitoes; or because, although infected, their powers of resistance were equal to the occasion, and no clinical symptoms ensued. Evidence points to the fact that the number of cases in which the natural resistance was reinforced by taking quinine was very limited. Captain Threadgold also states that he has come across no evidence which leads him to suppose that quinine is any more efficient in preventing relapse than it is in aborting the initial attack. As to the variably clinical results obtained from the administration of quinine, Captain Threadgold states that the key to the problem undoubtedly lies in the constitution of the patient and in his state of health at the time of infection and subsequently. Under good social conditions intermittent malaria tends to cure itself, whether quinine be given or not; but in a patient whose natural resistance is low, no marked benefit will result from the administration of the drug. Examples taken from the literature would seem to indicate that quinine may have an adverse effect on the general course of malaria, and so far as the allied armies in Macedonia are concerned, there is every reason to suppose that quinine taken daily over periods of many months has increased the severity and chronicity of the disease in a certain proportion of cases. Taking one thing with another, the available evidence indicates that in Macedonia, at any rate, the disadvantages of quinine prophylaxis outweigh the advantages. Captain Threadgold therefore concludes that small doses of prophylactic quinine—not too long continued—are of proved utility to the natives of malarial countries, both in the absence of antimosquito measures and when such measures are incomplete; and that quinine may be given with advantage to immigrants under the following conditions: (a) During short journeys when conditions with regard to mosquito prophylaxis are less favorable than usual; (b) an occasional dose after an unusually tiring day; (c) an occasional course as an additional precaution in spite of efficient mosquito prophylaxis in the case of nervous people. Speaking generally, however, it may be stated that quinine prophylaxis is usually a bad investment for immigrants in the absence of protection against mosquito bites. Captain Threadgold adds that in non-immune armies operating in highly malarial countries, although the difficulties may be great, the failure of quinine prophylaxis shows that more serious efforts must be made in the way of efficient mosquito prophylaxis and gives a few methods of procedure with a brief discussion of their value.

1. **Intravenous Injection in Wound Shock.**—Professor W. M. Bayliss prefers to use Captain Cowell's term "Wound Shock" rather than "traumatic" or "surgical" shock. Referring briefly to primary shock, he shows that this tends to lessen hemorrhage and that, if the patient is kept warm and quiet, the blood pressure may return to normal. Partial recovery, however, may be followed by secondary shock, to which Professor Bayliss devotes more particular attention. The actual nature of wound shock and the immediate cause of low blood pressure are still obscure. The following conditions, however, may be excluded: Yandell Henderson's acapnia; Crile's adrenal exhaustion, because adrenalin is present in excess at the onset of shock; exhaustion of the nerve centers, inasmuch as the reflexes are not diminished to any important degree except when the blood pressure has been low so long that the centers are paralyzed from oxygen want; cardiac failure; and paralysis of the arterioles or veins, especially of the abdomen, because direct observation during laparotomies fails to show any abnormal vascular distention. The explanation most in favor is an accumulation and stasis of blood in the capillaries so that it is as effectively removed from currency as it would be by bleeding—Cannon's exemia. With this deficiency of the circulating blood the blood pressure is naturally low, and as a result the tissues suffer from oxygen starvation, the vasomotor and respiratory centers begin to fail, and being directly dependent on the blood pressure, the excretion of urine and of acid and toxic products is diminished. After a careful consideration of the question of "acidosis" Bayliss concludes that it is not a serious factor in shock and that alkaline injections are not indicated. The existence of decreased bicarbonate blood content, however, is a sign of defective oxygen supply. Injections of alkaline solutions are of small and temporary value only, and the slight effect they have may well be the result of the volume of fluid introduced. Should the use of bicarbonate be thought necessary, it should be given by the stomach or rectum; it has, however, not yet been demonstrated that the symptoms relieved by bicarbonate would not be more definitely cured by raising the blood pressure. In principle it would seem to be a mistake to reduce the slight acidity in the blood, since this is of value in stimulating the respiratory center, and there is no evidence that the slight increase of hydrogen ion concentration which is present in some cases of acidosis, but not in all, is in any degree harmful in itself. The main factor in the successful treatment of shock is to ensure an adequate supply of blood—that is oxygen—to vital organs, especially of the nerve centers. Vasoconstrictor drugs cut off the access of blood to the tissues and are therefore inadvisable. It has naturally been assumed that the best means of raising the volume of the circulating blood is by means of transfusion, but, contrary to expectation, experiment has shown that a solution of gum arabic injected intravenously in most cases is not inferior to blood. The explanation of this appears to be that in ordinary conditions there is a sufficient reserve of hemoglobin to keep the tissues provided with oxygen, even with a diluted blood, provided the blood pressure is not too low and the patient is kept at rest. The nature and composition of the substitute for blood are important factors—Ringer's solution leaves the vessels in half an hour or so, and as the blood pressure then falls to its former level or even lower it is useless; hypertonic salt solutions also are of temporary value only and are liable to be followed by a greater fall in blood pressure; and the addition of calcium salts to Ringer's solution has been found to be of no advantage. A colloid with an osmotic pressure is required, and this is provided by a 6 per cent. solution of gum arabic with 0.9 per cent. of common salt. This does not leave the blood vessels or produce any bad effects, such as hemolysis, agglutination, thrombosis or anaphylaxis; it maintains the blood pressure indefinitely, and

has the advantage of easy preparation. Its value is most strikingly demonstrated after hemorrhage, and the cases reported by Captains Cowell, Drummond, and Taylor have shown its utility also in other forms of shock. It is not to be expected that it will be of avail when the bulbar centers have lost their excitability; even blood is useless in such cases. In cases where grave hemorrhage has occurred Professor Bayliss considers that transfusion of blood is the procedure to be adopted whenever possible.

Berliner klinische Wochenschrift.

March 25, 1918.

The Presence of Spirochetes in the Cecum in a Case of Multiple Sclerosis.—E. Siemerling refers to the researches of Kuhn and Steiner, who were able to transmit an inoculable disease in series to rabbits and guinea pigs. The benighted reviewer, however, prefers transfusion characterized by paralysis. An examination of the blood from the portal vein showed the presence of the spirocheta in every examination. The virus was derived from a patient afflicted with multiple sclerosis. The infective etiology of the affection is corroborated by the observations of Spittler and Dürck, who were able to incriminate malaria in some instances. The patient studied by Siemerling offered the characteristic signs of the affection, viz.: paraplegia, strabismus, disturbances of speech, intentional tremor and absence of the abdominal reflexes. He died from facial erysipelas. At autopsy numerous small foci were found in the cortex and white matter. Only two of the preparations examined in the dark chamber contained living spirochetæ. On the other hand, preparations stained with collargol or van Giesma did not reveal the organism.

Strangulated Diaphragmatic Hernia Following a Thoraco-Abdominal Wound.—Posner and Langer report the case of a soldier who recovered from a bullet wound of the thorax and abdomen. There had been a perforation of the diaphragm and a tangential wound of the spleen, followed by a pneumothorax. After this the subject was able to serve for seven months in an infantry regiment. Then, after an aspiration of the thoracic cavity, the splenic angle of the colon passed through the diaphragmatic aperture. This resulted in phenomena of intestinal occlusion, preceded by a phase of abdominal pain, although the abdominal parietes remained soft. The patient died on the operating table. In such cases the writers suggest besides radiography, which was not resorted to in their case, that it is well to take into consideration the dyspnea which accompanies the abdominal symptoms from the viewpoint of diagnosis. [The French surgeons have operated on a fairly large number of diaphragmatic herniæ from bullet wounds, and have pointed out the *rarity* of thoracic symptoms.]

Münchener medizinische Wochenschrift.

March 26, 1918.

True and False Sporadic Scorbatus.—Morawitz in the first place shows the reality of sporadic scorbatus arising in certain conditions which certainly speak against the infectious origin of the affection and are in favor of an alimentary origin. On the other hand, certain cases of purpura of the Werlhof type may be likened to scorbatus and simulate it, even so far as to include the changes in the gums. It is just to such a similarity that is due the idea of the infectious nature of scorbatus. A distinction is easy to make, however, given the case history, the clinical manifestations (therometric curve, fever being the exception in scorbatus) and the good effects or failure of suitable food. The writer has noted that the changes in the gums in scorbatus are not as constant as is generally supposed, while from the standpoint of the increase of the affection on account of circumstances arising from war conditions he declares that food restrictions have not had any marked effect. The writer has noted that scorbatus is absolutely exceptional on the occidental front [the reason for which he omits to state, and for good reason, as it would be only one more proof of plunder and ravage of the German army], while on the oriental

front the disease was quite extensive among the civil population, particularly during springtime and the beginning of summer, and he goes on to say that again in this instance the condition was not that of an epidemic, but the result of food conditions, both potatoes and beets being scanty on the oriental front after the Austro-German troops had cleaned out the country they invaded. This article concludes with the statement that canned vegetables do not prevent scorbutus on account of the necessarily high temperature required for their sterilization (one hour at 100° C. and one hour at 120° C.), which destroys the antiscorbutic ingredients, as has been demonstrated for experimental scorbutus in the guinea-pig.

Two Cases of Defibrinated Blood Transfusion.—Teske collects the blood in a heated recipient, floating on heated water. The blood is then deprived of its fibrin and injected (transplanted) intravenously. The writer advises this treatment in traumatic shock, even when loss of blood was not excessive, although he apparently has had no experience in the matter. The cases in which Teske has used it have been a post-traumatic suppurating arthritis of the knee with general mental depression and a case of serious nephritis with pulmonary edema. In the latter case the patient was better for the treatment, at least Teske thinks so, but we would add that the amelioration was only transitory.

The Treatment of Tuberculosis with Friedmann's Remedy.—Strauch and Bingel are extremely skeptic as to the efficacy of this medicament. Of the thirty-nine cases of tuberculosis submitted to Friedmann for treatment only those which were considered by Friedmann to be too far advanced for his treatment showed some improvement! One other case which was treated by Friedmann showed some improvement on the day that an abscess, which had developed at the site of the injection, was incised, thus giving exit to the medicament!

The Classification of Pulmonary Tuberculoses into Categories.—Two papers are offered on this subject, the first being by H. Ribbert, who, in a pathological study, considers especially the primary localization of the tubercles in the ordinary forms of tuberculosis. The bacilli become fixed, in the first place, in the alveolæ and bronchiolæ and there produce an exudation. This is in turn replaced by granulation tissue or may even pass to the caseous state. In both the latter processes the processus extends to the surrounding alveolæ without, however, involving an entire acinous territory. The processus has a tendency to surround a bronchiolus. The writer maintains these findings in opposition to the description given by Nicol and Aschoff, who uphold the tuberculous processus has a peri-acinous localization. As conclusions, Ribbert proposes to classify the tuberculoses into: (1) Cirrhotic and cicatrizing; (2) granulo-exudative, and (3) exudative. The prognosis depends upon the diagnosis of either one of the above three classes. The writer then offers up the prayer that radioscopy may be so improved upon that one may be able to distinguish the indurating processes from those of a caseous nature. The second paper on the same subject emanates from A. Baumeister, who comes to diametrically opposite conclusions. He points out that pathological observations never satisfy the clinician, who follows the general evolution of the disease and not the description of a momentary phase. He then outlines a general plan for the classification of tuberculous patients, such for example as: (1) Indurating tuberculosis of the right median lobe with a latent tendency, or (2) pneumonic tuberculosis opening into the upper left lobe, with a progressive tendency, etc., etc.

The Vitamines and Their Relation to Metabolism.—R. Kleissl, referring to the considerations in his paper in the previous issue, exposes the mechanism of the destruction of the albumins during cell activity and

the part played by certain intermediary products in life in general as well as in the rather more special activity of the endocrine organs. Tyrosin, whose affinity with the thyroid and suprarenal capsule is well known, appears more especially as the most indispensable amine acids. To its absence is due the clinical picture of the "avitaminoses."

How to Recognize Old Diseases of the Ears.—M. Falta, from the viewpoint of military examination, indicates the various lesions for detecting the length of time that a lesion of hearing has been present. They are as follows: (1) Bone cicatrices of the mastoid; (2) contraction of the auditive canal, without acute inflammation; (3) red color of the tympanum, particularly behind the incus; (4) thickening or thinning of the tympanum, with calcareous deposits; (5) immobility of the ossicles; (6) dry perforation, with epithelization of the tympanic cavity; (7) cicatrized minute perforations; (8) adhesion of the tympanum to the internal wall of the cavity; (9) polypi growing in the tympanic cavity; (10) chronic rhinopharyngitides and adenoid vegetations.

Acclimatization.—De Langen and Shut of the Dutch East Indies speak first of the initial period of malaise which follows removal to the tropics. The reserves of the individual are drawn upon during the process of acclimatization. The latter must not be confounded with mastery of tropical hygiene for this is active and voluntary and is considered fully by the temporary sojourner. When things go wrong it is bad hygiene, not want of acclimatization which is most at fault. Naturally it is hygiene to guard against some of the perils incidental to acclimatization. Thus if the actinic rays are an obstacle to the latter there are means by which the danger is minimisable. In the temperate zones a man does no less—he does not expose himself directly to the noontide summer sun. In the tropics it may be necessary to remind him that his exposure to these rays is greater and more constant. This is hygiene, not a seasoning process. The pulse beat increases in frequency at the outset, but gradually becomes normal—this is a true seasoning process but of no special significance. It may remain high in the individual case and the temperature is higher by 0.7°-0.8° C than that of the native. The bloodpressure is said to be increased in the emigrant after he lands but while it is notably higher than in the native it is not high by European averages. The cholesterine of the blood seems to fall below the European standard some 50 per cent. or at least this is true of the natives. Conversely the latter have more oxidizing substances in the blood and this is true of the emigrant after acclimatisation.

Post Operative Psychoses.—Tramer refers to the great infrequency of this condition which justifies the publication of a case. He has seen two examples during two years' service in an insane asylum. The first was in a laborer's wife with history of nervous manifestations with implication of the psyche. The latest of these had reference to an excess of religiosity during her last confinement, about seven weeks before the operation for appendicitis. Psychosis on fifth post operative day just after removal of sutures. The attack was acute, requiring incarceration. She tore away the wound dressings and had to be fed forcibly. Within a week she had to be sent to the asylum. The leading symptoms on admission were marked motor unrest, lively hallucinations with religious content, marked disorientation, sudden change of temper. These symptoms persisted for six weeks, with periods of euphoria and transitory Katatonic phenomena. At this period the content of the hallucinations became less religious and the sensorium became clearer until complete insight resulted. She was discharged cured and when seen eight months later had remained in ex-

cellent mental health despite severe exertion and an attack of jaundice. The case is summed up as follows: hereditary taint slight and probably negligible. Nervous system metastabile, presenting episodes characterized chiefly by confusion. The determination to religiosity came apparently from religious sisters who attended her during her last puerperium. The post-operative attack was perhaps traceable to the stage of excitation of the ether anesthesia for the appendix operation. She was also very anxious before operation. Her last labor, already mentioned, had been unusually severe and she had nursed her child up to the time of operation. The outbreak of the psychosis was attended with fever, the wound up to that time having been sterile. Later infection was super-added. The type of psychosis was very largely exogenous, ranging itself in part with the febrile and toxic infectious types. The second patient, also a laborer's wife, had a frank hereditary taint—in fact the unsound among her immediate kin outnumbered the sane members. She herself, however, remained intact mentally up to the time of an operation for goitre, although she had been subjected to exhaustive physical labor. Before operation she had been extremely anxious. The psychosis perhaps began at once after the intervention but did not become evident to the surgeon until the sixth day. The symptoms at first comprised catatonic excitation. The author thinks a post-operative bronchopneumonia was not the determining factor. The secondary symptoms were those of a defective mental state with prognosis fair.

February 16, 1918.

Congenital Bronchiectasis with Tubercle Bacilli in the Sputum.—Bergstrand relates an autopsy case in a woman aged 24. The histological picture comprised purulent bronchitis, bronchiectasis, broncho pneumoniae abscesses with attempts at repair alongside of alveolar emphysema. The elastic tissue showed such a degree of atrophy that it could not be explained by the presence of a chronic, inflammatory process. In the lung tissue were many pin head sized, intercommunicating cavities of cystic character, the walls of which contained concentrically arranged smooth muscle fibres and were lined with cuboidal epithelium. These cavities communicated with the alveoli but not directly with the bronchi. The author believes that these spaces were of congenital origin and denies that they could be due to a chronic inflammatory process in an emphysematous lung or an acquired bronchiectasis. A prenatal (syphilitic ?) inflammatory process would account for the condition and there was moreover a suspicious lesion in an upper lobe of the lung—a coagulation necrosis resembling a gumma. Congenital lack of elastic tissue would also help to explain the occurrence of a fetal bronchiectasis. The inferiority of the lung parenchyma may also have led to a compensatory dilatation of the bronchioles. In the cadaveric sputum there were masses of acid fast organisms which were apparently tubercle bacilli. The clinical diagnosis had been pulmonary tuberculosis. These were also found throughout the lung tissue. Further studies of this germ threw doubts upon its nature. The tinctorial qualities underwent a change. They were not pathogenic to guinea pigs and the author suggests that they were perhaps only a species of streptothrix. Numerous other flora were found in the bronchi—the spirochetes and fusiform bacilli of Vincent, staphylococci, and blastomyces.

On the Significance of the Canaliculi in the Mechanism of Lacrymation.—Frieberg gives a condensation of an article written by him last year for the *Zeitschrift für Augenheilkunde*. In 1878 Krehbiel stated that fluid dropped in an eye which remained open disappeared but slowly. In the absence of winking it was simply aspirated into the canaliculi. The author takes up this claim that the latter exert a pumplike action but is undecided as to whether the role of the lacrymal sac is active or passive. He also shows that the action of winking activates the propulsive power of the tear passages.

SECTION ON DISEASES OF CHILDREN.

First Day, Wednesday, June 12.

DR. LAURENCE R. DEBUYS OF NEW ORLEANS IN THE CHAIR.

Chairman's Address: Conservation of Child Life, a National Responsibility.—Dr. LAURENCE R. DEBUYS delivered this address, in which he said that a point they were very likely to forget was that they all had been babies themselves at one time, at least he felt that the medical profession forgot it, judging from the lack of interest that they evinced in the infant. The medical profession must interest itself in saving the lives of our babies because it was upon the babies that the future life of our country depended. The medical profession and the pediatricist must be the advisers of the lay public. Naturally the members of the medical profession liked to become officers in the Medical Reserve Corps and to know that they were serving their country, but the medical men who were pediatricians and engaged in child welfare work should feel that they were rendering as great a service to the country as though they were serving in the Medical Reserve Corps. We should benefit by the experience of the European countries that now recognized the necessity of keeping the birth rate as far above the death rate as possible. In order that any work might be successful the value of a proper foundation was recognized. This was equally true in the building of the nation. The large loss of life from prematurity, death *in utero*, infant mortality, and the finding of 25 or 30 per cent. of the drafted men physically unfit in some respect had centered attention on the necessity of looking to the foundation of our nation, its children. Each period of the infant's life should be looked to, the prenatal, even the pre-conceptional, the parturitional, the period of infancy, the pre-school age, the school age, and the adolescent period. That this might be done effectively, the cooperation of the lay public and its various organizations was essential, but it was equally important that their efforts should be guided by those specially skilled in caring for mothers and children. It should be understood that the physicians who give this advice and guidance should be recognized as doing a special war work. The nation lost annually, according to the most reliable statistics obtainable, 540,000 infant lives. Of these deaths it was estimated that 250,000 were preventable. We were going to try to save 100,000 of these babies. There was nothing that we could do for our soldiers at the front that would help them more than to have them feel that their wives and families at home were well cared for. Dr. DeBuys presented statistics to show that the saving of 150,000 lives would mean in twenty years an equivalent of \$3,014,000,500, according to the value placed on the life of a human being by the estimate of Dr. Irving Fisher. Later this saving would be further increased because the children saved would later become parents. Dr. DeBuys urged a uniform registration law for births and deaths which should be under Federal control. Experiences with the selective draft had brought out more strongly than ever before the need of a complete birth registration. In the child welfare work that was to be done the great responsibility lay on the pediatricians. They should openly recognize this responsibility, not as a way of disposing of the matter, but for the purpose of placing themselves in a position to take an active part in the work.

Infant Mortality Campaign in France.—Dr. PAUL ARMAND-DELILLE of France presented this communication, in which he reviewed the history of child welfare work to show that before the war in France, as in all countries, infant welfare work was being carried on in an extensive way, and that infant mortality had con-

tinued to decrease until the time of the war. Since the beginning of the war they had again noted an increase in their infant mortality rates. Not only had France long taken an interest in infant welfare work, but since 1846 it had taken an interest in prenatal work. In the above named year a great philanthropist of Mulhouse, in Alsace, founded the Association for Pregnant Women, which gave an indemnity during the period of confinement and nursing to the working women of the manufactories. The women gave a small amount of money annually which was increased by charitable gifts and this formed a fund which permitted of all the participants having at the moment of accouchement the services of a physician and of a midwife, and also the receipt of an allocation which permitted the woman to remain at rest for some weeks after confinement. This measure had caused a decrease in infant mortality. France possessed two laws destined for the protection of early childhood. The first, the Loi Roussel, aimed to protect children placed by their parents in nursing homes. Every child confided to a wet nurse, to an ordinary nurse, or to another woman for care, came automatically under Government supervision. A second law, that of Senator Paul Strauss, was adopted shortly before the war, in June, 1913, with the addition of certain amendments in June, 1914. This law had to do with the protection of the mother during her pregnancy and with the mother and child during the first four weeks after birth. It permitted the mother to have complete rest and to begin the nursing of her child under the best circumstances. The Government also provided a certain allocation for mothers during the first four weeks preceding and following confinement. There also existed a law for the aid of large families. Dr. Delille also described the Consultations de Nourisson, founded by Paul Budin, which had now become very popular throughout France. Only three things were necessary for the creation of a consultation de nourisson, a balance, or scales, a milk sterilizing apparatus, and a physician. There was generally one other essential factor, and that was the visiting nurse. Since the beginning of the war "Chambres d'Allaitement," or "Rooms for Nursing," had been established in the munition factories and were made obligatory. In each factory there were set aside one or more rooms, well aired and kept perfectly clean, where the women brought their children in the morning and where they went to nurse them during the day. There was also added a room for the sterilization of milk and a play room for the older children. In connection with this there were dining rooms for mothers and for the children where a meal could be procured at very slight cost and where suitable menus for mothers and for children were served. There was also an isolation room for children who were ill. After describing a number of institutions in different parts of France that were engaged in caring for infants and children, the essayist described the conditions that had come about since the war as the result of taking all the medical men between the ages of 25 and 50 years and of diverting much money that formerly went to child welfare work to immediate needs of war work. In 1917, they found themselves in particular difficulties in their reorganization of the fight against infant mortality. At that time the American Red Cross arrived in France, with its special department, the Children's Bureau. After having responded to the immediate needs at Toul, Nesle and Evian, the American Red Cross had organized the Infant Welfare Exhibit at Lyon. This had met most astonishing success. At the same time they had organized a course for the training of visiting nurses. The director of Public Hygiene, in the Ministry of the Interior, was entirely disposed to cooperate with the Red Cross. His administration would institute an investigation in order to establish not only the list of existing organizations interested in child welfare work, but would indicate the districts where the need was most urgent and would assist in the reorganization in the various departments, cities, and communities. Dr. Delille also told of the care that was being given the tuberculous in France and more particularly the provisions that were made for taking children from families in which there was open tuberculosis. The results of this work had been most encouraging. In a series of children investigated, of those left with tuberculous

parents 40 per cent. died and among those surviving the morbidity was 60 per cent., while among children removed from homes in which tuberculosis was present the mortality was only 0.02 and the morbidity 0.05. A number of institutions in which bone and joint tuberculosis were treated by the Rollier method were described.

A Report on Children in the War Zone.—Drs. JULIUS P. SEDGWICK and N. O. PEARCE presented this paper, which was read by Dr. Pearce, in which they told of their work among the refugees in France. Dr. Sedgwick had first been located in a Red Cross hospital at Toul where he had the care of 200 refugees. This they were forced to evacuate, as several of the children were victims of gas and they were under daily bombardment. The conditions under which the refugees were forced to live were described. Sometimes twenty-five or thirty women and children occupied one small, poorly ventilated room, and the food, though plentiful, was of poor quality. Of the first 200 cases they had handled, 93 per cent. of the fathers were in the Army, 13 per cent. of these fathers had been killed, and 5 per cent. were prisoners. Of these children 95 per cent. were breast fed. A comparison of these children with the averages for American children showed that the American children were taller. The French children had somewhat larger heads, probably due to slight rickets in early life. Forty-one per cent. were affected more or less severely with rickets, judged by American standards, and 46 per cent. were undernourished. Sixty-one and one-half per cent. had impetigo. It was interesting to observe that the French children were vaccinated against smallpox in three places, and 95 per cent. of the children gave a history of vaccination. The percentage affected with other conditions was as follows: Hydrocephalus, 1 per cent.; conjunctivitis, $7\frac{1}{2}$ per cent.; inflammation or discharging ear drums, $14\frac{1}{2}$ per cent.; defective teeth, $43\frac{1}{2}$ per cent.; enlarged tonsils, 47 per cent.; adenoids, 25 per cent.; enlarged cervical glands, 41 per cent.; enlarged epitrocler glands, 15 per cent.; Harrison groove, 50 per cent.; marked rosary, $8\frac{1}{2}$ per cent.; Despine's sign, $22\frac{1}{2}$ per cent.; hearts normal in outline, 100 per cent.; heart murmurs, 5 per cent.; scoliosis, 33 per cent. This was attributed to the fact that the children had to perform heavy tasks beyond their strength. In 32 per cent. there were exaggerated knee jerks. There was very little tuberculosis among these children, less than one-half of 1 per cent. This same percentage had been maintained among other groups of French children.

Children's Year Program for Child Conservation in War Time.—Dr. GRACE L. MEIGS of Washington, D. C., outlined the plans of the Children's Bureau. She said that the foreign countries, which had been at war for three and one-half years, had realized almost from the first that the preservation of the lives of babies, children, and their mothers was war work of the utmost importance. Effort along the lines that had proved successful in peace times had been redoubled during the war in most of these countries in spite of great difficulties encountered, the fact that so many physicians and nurses had been called into military service, and that popular interest had been diverted to war work which made a more dramatic appeal than did the child welfare work. After outlining the plan of organization by which the Children's Bureau was conducting the present campaign, Dr. Meigs stated that the first feature on the program, the weighing and measuring, had excited considerable interest, about 5,000,000 families having been enrolled. In many localities there had been an increase in the number of infant welfare stations. In closing Dr. Meigs said she believed that later on the infant welfare work would be considered one of the great lines of progress that had been developed from the war.

Medical Work Among the Civilian Population in France.—Dr. WILLIAM PALMER LUCAS described the work he had been engaged in in France and gave a lantern slide exhibition which brought out in a vivid way the condition of the people and the work that the American Red Cross was doing. They had first organized the Central Hospital Unit, where they had to begin with 50 children and later 200 hospital beds, of which 20 were for maternity cases. He had also been stationed at Evian, where the repatriates were returned to

France from the occupied territory of France and Belgium. They came around through Switzerland and were mostly old men and women and little children, or women with young children who were unable to work. All other women and men between the ages of fourteen and fifty-five were kept in by the enemy. At Evian Dr. Delille was responsible for the most wonderful organization in the world for protecting France from the introduction of contagious and infectious diseases by these refugees. They received steadily from 500 to 600 refugees daily, and all these were given a bath and had their clothing sterilized in an autoclave. They had a large isolation hospital for contagious diseases where they had had from 1,200 to 1,400 cases, and among these only 2 per cent. cross infections. The beds were separated merely by linen sheets. This spoke well for the efficiency of American nurses. At Evian, where the repatriates were coming in and being reunited to their families, the work was most dramatic, but Dr. Lucas said the most of the work he had been doing was the ordinary work that was to be done in a civilian population where the doctors had nearly all been taken away. The work among the civilian population was increased because of the war. For instance, in Lyons before the war the population was 450,000; it was now 800,000 and there were no new housing accommodations. Before the war there were 5,000 women in the munition works; to-day there were 800,000 women in the munition works. Dr. Lucas said he had been no more inspired and impressed by the men at the front than by the fine spirit shown by the women workers in these munition factories. They were determined and uncomplaining, and there was no discouragement shown. The result of these conditions, however, would be to still further decrease the birth rate of France. The birth rate was now 40 or 50 per cent. below normal. That meant that every baby saved was from 50 to 100 per cent. more important than before the war. One of the finest features of the work they were doing was the keeping of the most wonderful card index in the world which enabled them to keep track of every refugee and to give information regarding their families. Dr. Lucas described the clinics that had been started in the larger cities and the traveling dispensaries and traveling exhibits that were being sent to the smaller towns. He told of the great Child Welfare exhibit that had been given in Lyons in April and the enthusiasm with which it was received. At the opening representatives of the Church and State were present, and the French people were doing all they could to cooperate with the American Red Cross. Dr. Lucas showed the posters being used in the Child Welfare campaign in France, told of the interest that the American soldiers were taking in the French children and that some companies were assuming the responsibility for one or more French children. The Red Cross was doing a great work in sustaining the morale of the French people, and if it were doing nothing more than this, though as they all knew it was doing much more, it would amply pay for all effort and money expended in carrying on the work.

Dr. RAYMOND HOOBLER of Detroit said that if the war continued our women would have to go into the industries also and that we would be confronted with the same problems as France was now attempting to solve; it was therefore the part of wisdom to get to work at once and not wait until the load became too heavy before getting under it. He suggested that it would be a good idea if each of them would go home and see to it that in towns where there were factories the Board of Health took a census of all the women in the factories and would put the communities in which factories were located in a position to care for their women workers and their children. The crèches in connection with the munition factories that Dr. Delille had described were worthy of imitation.

Dr. EDGAR J. HUENEKENS of Minneapolis emphasized the importance of proceeding immediately to extend the child welfare work that we were now doing into the smaller towns and rural districts as well as in the larger cities.

Dr. LAWRENCE T. ROYSTER of Norfolk, Va., urged the taking of a census in every community of all the children and keeping records so that each child could be followed through infancy, the pre-school and school age.

Dr. CHRISTISON of St. Paul disapproved of the way in which the work was being carried on by the women's committees and stated that he knew of one place where an osteopathic woman physician was in charge of the work. He expressed his surprise that the Bureau at Washington had not been more energetic in seeking the assistance of recognized pediatric authorities and the cooperation of the local health boards.

Dr. MEIGS, in closing, said that the Bureau had sought the cooperation of the State Health Boards and the pediatricists, but the children's specialists thought the weighing and measuring was not accurate enough and had not encouraged it. She admitted that it was not all that they desired, but said that it served to focus public attention on child welfare work which was so vital at the present time. She did not think it was necessary for American women who had small children to go into munition factories at the present time, and urged that they remain at home and do a greater service for their country by giving their young children the care they required.

Dr. LUCAS said the conditions in France were such that the women had to go into the factories, that it was not a matter of choice with them but of grim necessity. He believed that the pediatricians should encourage this work that the Children's Bureau was doing and take more interest in the sociological and economic side of child welfare work.

Clinical Supervision of the Well Baby During Its First Year.—Dr. HENRY H. YERINGTON of San Francisco presented this paper, in which he called attention to the lack of constructive work in the ordinary clinic. He described the plan of organization of the clinic with which he was connected, the pediatric clinic of Stanford University, which permitted one man to follow the cases through their treatment. In commenting on the need of supervision for the well baby, the speaker stated that a few years ago in a foundling asylum in San Francisco the mortality was 59.7 per cent. They closed the institution and boarded the infants out, and the mortality dropped to 12.5 per cent. With more careful supervision they had reduced that mortality to 2.57 per cent., whereas the mortality for the city of San Francisco as a whole was 8.7 per cent. They had conducted the clinic for well babies since last September. The clinic included a prenatal clinic, maternity service, outpatient clinic, the hospital and the follow-up system. In this clinic there was a very close association of the prenatal and adolescent work. Complete records were kept by a social service worker, and careful supervision of the patients was carried out in reference to home surroundings, the milk supply, etc. The social service department during the time the clinic had been in operation had made 2,146 visits. Of 290 cases cared for in the maternity hospital 67.8 per cent. returned to the clinic for supervision of the babies. The babies were brought to the clinic once a week for the first three weeks, once every two weeks from the third to the sixth month, and once a month from the age of six months to one year. They had found their babies a little above the average weight at birth. In determining whether the mother's supply of milk was sufficient for the baby they had found that the examination of the breast milk was of slight value compared with the clinical signs of a diminished milk supply. Modified milk was given when breast feeding was impracticable, and cane sugar was used with either maltose or dextrose. A very generous diet was given and both the caloric and percentage methods taken advantage of in this work. They felt that they were organized for a big work in the campaign against infant mortality.

Dr. WAHRER of Madison, Iowa, said that a few years ago a clinic for well babies would have appeared foolish, for what could a well baby want with a clinic? What appeared foolish in one generation became a real necessity in the next. Thus it was that we progressed. He compared conditions at the present time when every mother was supposed to get care during the period of pregnancy with conditions thirty-five years ago, when the doctor seldom saw the woman until she was in the second stage of labor. When a man was called out in those times in a remote rural district he did not know whether he was going to find a broken leg or a confinement case. Fortunately those remote rural districts were becoming very rare, and the mothers were being

taught that they should seek advice early in pregnancy.

Dr. HERMAN SCHWARTZ of New York said that he had had a well baby clinic in New York for the past twelve years. During that time they had taken records of about 11,000 babies, and they had the actual social histories of about 10,000 families in New York. The histories of these 10,000 families had been collected by the same social worker and were essentially accurate. Interesting statistics in regard to this series of cases were cited which showed that of 20,000 pregnancies that occurred in these families 5,000 of the babies died, a loss of 25 per cent., as the result of miscarriage, still birth, and infant deaths. The rate of miscarriages was 80 per 1,000 pregnancies, and the infant death rate 126 per 1,000 births. From all causes there was a death rate of 178 per viable pregnancies.

Report of Three Years' Clinical Experience with the Feeding of S. M. A. (Synthetic Milk Adapted).—Dr. HENRY J. GERSTENBERGER of Cleveland presented this communication, in which he reported the practical and clinical results of feeding about 400 infants with S. M. A., an artificial food which was different from other previous artificial milks in that for the first time it represented an attempt to adapt the fat of the artificial milk to the fat of woman's milk. The synthetic milk consisted in a combination of skim milk, milk sugar, and homogenized cod liver oil. The children were under the supervision of several clinics of Cincinnati. Of these infants 74 were removed from the food before the sixth week of feeding for various reasons, such as because the mothers were not carrying out instructions or were able to nurse the babies again. A few discontinued the use of the food because it was claimed that it caused dyspepsia, but these children were not under the writer's observation, and he had never seen an instance where this food caused dyspepsia. There were 311 cases that received the S. M. A. for more than six weeks. Of these 11 died, but in all instances the cause of death had no relation to the food. The stools in approximately 80 to 85 per cent. were normal, and in 10 to 15 per cent. constipated. In other words, entirely different than the stools obtained by Bahrdt with Friedenthal milk and by Schloss with his adapted milk containing milk sugar. This observation proved that Schloss' assumption that the high lactose content of the food was responsible for the dyspeptic stools, the lack of appetite, and the vomiting, could not hold good. In 11 babies from 12 to 34 weeks on the S. M. A. the hemoglobin determination remained normal. The electrical excitability in every instance remained normal. The average gain in weight per week compared favorably with that of normal breast-fed infants. Charts presented showed the details in this respect. The measurements showed that the babies grew like normal breast-fed infants. It was possible to obtain perfect nutritional results as far as they knew to-day without the aid of butter fat in a food, if that food was similar to breast milk in its protein. The feeding was not accompanied by rickets, spasmophilia, or anemia. This milk pasteurized would produce scurvy unless an antiscorbutic was administered. A practical advantage of using the S. M. A. milk lay in the fact that it enormously simplified infant feeding, especially in prophylactic dispensaries and infant welfare stations, inasmuch as it required only a change in quantity, so that the physician really fed his infants as if he were feeding breast milk.

Dr. JOHN ZAHORSKY of St. Louis said that he had been working on the same problem, that of increasing the amount of fat in skim milk used for infant feeding. He recalled that he had read a preliminary report before the section in which he related his experience in using swine fat as a substitute for butter fat, but he had not used completely skimmed milk. He felt that if they had a good percentage of fats in the milk fed to infants they would not have to have so much carbohydrate. In feeding lard the vitamins were lacking and these had to be supplied. Dr. Zahorsky said he thought Dr. Gerstenberger's artificial milk was better than the one he had experimented with.

Dr. ISAAC ABT of Chicago asked why they should try to devise a milk of this kind when they were getting good results with the various milk modifications that they had now.

Dr. FELLMAN of Milwaukee asked the essayist if he

had considered what effect simply adding codliver oil to a regular milk formula would have. He had found that simply adding the codliver frequently caused the child to gain and that had been done without emulsifying the oil.

Dr. WAHRER said we must not be captious or hypercritical. A milk which would be as easily adapted to the needs of the infant as this one was said to be capable of doing was the thing they had all been seeking, and they had not hitherto found it. It sounded like a beautiful dream; now the only thing that was needed he thought was to standardize the babies. He feared that was where the trouble would be found to lie. That was where the great trouble had always lain; we did not know how to standardize babies.

Dr. HERMAN SCHWARTZ of New York said he would like to have Dr. Gerstenberg tell a little more definitely what the indications were for the use of this milk. It was easily made, the cost was trifling, and as a substitute food it would have certain economic advantages. He would also like to know how long it remained fresh, and what the clinical results were in dyspepsia and intoxication.

Dr. GERSTENBERGER, in closing, said that in reply to Dr. Abt's question he did not agree with him that the simple milk modifications were always applicable. There were many instances in which it was very difficult to find a suitable milk modification, and it was almost impossible to find a milk modification that infants under one month of age took well. Of the children fed on modified milk mixtures there were not 95 per cent. doing well. A goodly percentage of the children fed on those mixtures had slight rickets, and the results were not as good as in breast feeding, when the milk was modified. This preparation came the closest to breast milk of anything they had yet used. In reply to the question as to what a homogenizer would cost, Dr. Gerstenberger said the cost was about \$1,200, and the cost of the milk was less than that of certified milk. So far as the practical results were concerned, he had been using it for three years in practical dispensary work, and he thought he had collected enough evidence in favor of this food to feel safe in advising its use. The milk was made of about one-third skimmed milk, 7 per cent sugar, and 3 per cent. fat.

Digestion of Fat by Gastric and Intestinal Ferment.

—Dr. JAY I. DURAND of Seattle presented this communication. He briefly reviewed some of the literature in reference to the digestion of fat by the gastric and intestinal ferments and described the method which he used in making his experiments, a modification of the Trauber method. He concluded as follows: (1) Stomach lipase followed by pancreatic lipase gave an increased rate of splitting over that given by either alone or both simultaneously. (2) The pancreatic lipase was destroyed during the action or so combined that its rate of action was greatly retarded. (3) This fact rather than any preparatory change in the substrate by the action of the gastric lipase probably explained the finding. (4) The duodenal lipase action was retarded when in the presence of gastric juice. (5) Duodenal lipase in an equal quantity of duodenal juice was 250 to 500 times as active as the gastric lipase in an equal quantity of gastric contents, when taken by the method used in the experiments.

Lumbar Puncture in Meningeal Hemorrhage of New Born.—Dr. JULES M. BRADY of St. Louis read this paper, in which he reported three cases of a series of nine meningeal hemorrhages in which lumbar puncture as a therapeutic agent was employed. In one case the convulsions were temporarily abated but infant developed Little's disease and died at the ninth month. In the other two cases lumbar puncture brought about a cure. One child was now three years of age; the symptoms were so typical that no mistake could be made in the diagnosis. Thirty c.c. of pure blood were removed by the needle on lumbar puncture. The distentions of the fontanelle receded, the infant became quiet, and there was no return of the convulsions. Its development to date had been perfectly normal. The third infant was now one year of age, the symptoms were mainly respiratory, but there were no convulsions. Four lumbar punctures were made in as many consecutive days and 240 c.c. of bloody spinal fluid removed. The recovery of the infant was a matter of the greatest

wonderment to all who saw it. To-day there was no evidence of spasticity of the infant's extremities or any mental impairment. These two infants belonged to the type of infratentorial hemorrhage which was not amenable to craniotomy as the hemorrhage was not accessible. In all cases of suspected meningeal hemorrhage lumbar puncture should be performed, as even in the supratentorial type of hemorrhage some blood cells must be found which would assist in making the correct diagnosis. In the infratentorial type of hemorrhage not only would there be almost a certainty of clinching the diagnosis, but the measure might be of definite therapeutic value, even resulting sometimes in a perfect cure.

Dr. FRANK C. NEFF of Kansas City said it seemed to him that this paper had brought up an important subject in connection with their present efforts to reduce the number of preventable deaths among infants. Intracranial hemorrhage was not rare at all in the newborn, although as a rule the pediatricist was only called to see infants with this condition when it was too late, and as a consequence we often had idiocy, palsies, and other conditions that could not be remedied. In acute meningeal hemorrhage certainly a correct diagnosis was of great value at the time it occurred, and this served to emphasize what they all knew, namely, that the pediatrician should have the supervision of the baby from the time of birth. If a surgical procedure was to be employed, it was essential that the diagnosis should be made early. Lumbar puncture was of great importance as a diagnostic measure, and blood would be present in the spinal fluid or not according as to whether the hemorrhage was above or below the tentorium.

Dr. FOOTE of Boston said that, without wishing to slander any other members of the profession, he thought the causes of intracranial pressure were not well understood by the general practitioner. Some only looked for these hemorrhages after forceps operations. They occurred frequently, however, in two classes of cases, after a long labor in which there had been a great deal of pressure, and in a class of cases in which there was no special condition to account for the hemorrhage. He believed that not all cases were due to maternal causes, and there were cases in which the hemorrhage was not from the meningeal artery but was simply an oozing due to a great permeability of the blood vessels. There was no question that these cases were greatly helped by relieving the intracranial pressure, and that lumbar puncture was a great aid as a diagnostic measure. In these cases it did not harm to use a blood coagulant or even to resort to transfusion.

Dr. NEFF of Kansas City referred to the use of pituitary extract and its effect on the newborn. He said he personally had seen more than one death from meningeal hemorrhage in cases in which this substance was used, and he thought that it should be put down as a cause of intracranial hemorrhage.

Dr. LANGLEY PORTER of San Francisco emphasized the fact that pituitrin might be a cause of meningeal hemorrhage.

Dr. DAVIS of Dallas, Tex., said he had seen some six or seven cases of meningeal hemorrhage in the newborn, and some four or five had come to operation. They were opened through the suture. It was possible to have the hemorrhage above the tentorium and yet not have a bulging fontanelle.

Dr. LAWRENCE ROYSTER of Norfolk said that one could not rely upon the bulging of the fontanelle as an indication in meningeal hemorrhage in the newborn; there was a boardlike feel that was more common than the bulging, regardless of where the hemorrhage was.

Dr. BRADY, in closing the discussion, said there was no question that bulging of the fontanelle was frequently absent in meningeal hemorrhage, but when it was present it was a sign that made one feel very certain of his diagnosis. Sometimes the patient would lie listless and deathly pale. Nothing was said about lumbar puncture in the textbooks; if this procedure would cure some of these cases they should know about it. If one found only a few blood cells in the spinal fluid it would indicate that the hemorrhage was high up, and then the surgeon was rather in the dark as to how to proceed, but it seemed to him that an incision

through the coronal suture was better than the operation that Cushing advised.

The Significance of Infection of the Accessory Sinuses of the Nose in Infants and Children.—Dr. ALBERT H. BEIFELD of Iowa City presented this paper. He stated that there was a possibility that the tonsils and adenoids, as a source of infection, was overemphasized. In the course of clinical investigation in cases of chronic deforming peri-arthritis he had found that the removal of the tonsils and adenoids did not control the disease process, and the focus of infection was still to be sought. In a number of such cases the accessory sinuses had been found infected, and after the removal of the focus of infection in that locality the disease had been arrested. He believed that the frequency of sinus disease was greater than had hitherto been suspected, and that the possibility of this as a source of infection deserved more attention. The focus of infection had been found in a series of cases such as cyclic vomiting, infectious deforming peri-arthritis, asthma, persistent cough, occult temperature, chronic digestive disturbance, pyelitis, and poor general health. In order to arrive at a diagnosis in these cases an x-ray examination and exploratory puncture might be necessary. Personal environment might play a part in the infection. There were some families that might be designated as catarrhal families. He had just had an instance brought to his attention in which three members of a family had sinusitis within a very short time. The symptoms of accessory sinus disease most frequently present were chronic purulent nasal discharge, sneezing, nervous irritability, and headache. He would not advise surgical treatment until medical means had first been tried unless the condition of the patient demanded immediate surgical relief. The non-surgical treatment would bring them to a discussion of vaccines; this he would not enter upon.

Dr. ROY N. ANDREWS of Mankato said that they were not only liable to overlook sinusitis but it was possible to have ethmoid disease in children. He cited the case of a child whose tonsils and adenoids were removed but the child was not cured until the ethmoid trouble was taken care of. Unfortunately nose and throat work was done by too many people. Frequently the upper part of the tonsils were left and with them the focus of infection. Nose and throat work should be turned over to capable men, and the possibility of accessory sinus infection should be borne in mind.

Dr. JOHN ZAHORSKY of St. Louis said that in many babies and young children after the removal of the tonsils and adenoids there would be a purulent rhinitis and he would like to ask whether this was a primary sinusitis or whether it was the result of the operation.

Dr. BEIFELD said that in speaking of sinus disease he did not wish to take up any of the surgical phases. In many of the cases in which a discharge persisted after operation syphilis was present, or a secondary infection was the cause of the slow healing. Again the discharge might be caused by the fact that there was a greater congestion after the operation and this might dam back the secretions and lead to infection. In cases of respiratory infection it was always well to bear in mind the possibility of sinus infection.

SECTION ON OBSTETRICS, GYNECOLOGY, AND ABDOMINAL SURGERY.

DR. BROOKE M. ANSPACH OF PHILADELPHIA IN THE CHAIR.

First Day—Wednesday, June 12.

Enterostomy and Enterocolostomy in the Treatment of Intestinal Obstruction Following Pelvic Operations.—Dr. BROOKE M. ANSPACH of Philadelphia delivered this address. Intestinal obstruction after abdominal operation was a very distressing occurrence. Points for careful observation were: the peritonealization of raw surfaces and closure of all openings into which the viscera might slip; the avoidance of intestinal trauma by handling during operation; and care in drainage, thereby insuring avoidance of infection. Owing to deficiency in blood supply, adhesions were likely to occur and the wall of the gut thus to become peculiarly susceptible to bacterial invasion. Measures of prevention

could be summarized as embracing the most scrupulous asepsis, the avoidance of trauma, and omission of too early catharsis. If the condition were immediately recognized, a very large proportion of the cases would recover. Difficulty in this early recognition was occasioned by the fact that the symptoms were often simulated by other conditions. Such symptoms as tympanites, acetoneuria, and ether vomiting were common to many other states. Three stages could be noted: the onset, the obstruction, the toxemia. Pain, distress, and vomiting, not relieved by gastric lavage or by enemata, were diagnostic signs, and if these were present, the diagnosis should be promptly made and operation performed. The second stage showed gangrene of the bowel, and in the third stage, the toxemia was acute. Often the obstruction was allowed to go 24 hours before operation. In volvulus the lesion was similar, but the condition was localized to one loop. The high type of obstruction in the small bowel was found to be much more fatal than that in the lower bowel. The toxins found their way into the blood by means of injury to the lining of the intestine; the poisons might rise from the secretory activity of the digestive glands or from bacterial activity, but as long as the mucosa remained intact they were harmless. Often, however, after the removal of the obstruction these toxic products were loosed by the peristalsis and the patient died of the resulting toxemia. In advising the operation of enterocolostomy, it was thought that this would give the bowel a chance to recover itself. In some cases the small intestine above was joined to the large intestine below. When the anastomosis was made to the sigmoid, enterotomy was not needed, but it was necessary in the case of anastomosis to the cecum. Results of the operation showed that the exclusion of part of the intestinal tract had done no harm and that enterocolostomy had a definite place in the treatment of acute pelvic obstruction.

Clinical Observations and Results of the Newer Methods of Operations in Congenital Pyloric Stenosis and Gastric and Duodenal Ulcers.—Dr. ALFRED A. STRAUSS of Chicago read this paper. Sixty-six cases surgically treated and thirty-six medically treated were reviewed. Three deaths were recorded following operation. Pyloroplasty was the method of choice, in which operation the pathological pylorus was reconstructed into the normal one. The mucosa was found infolded and was unfolded; it was shelled out and the pyloric tumor split and spread out. With simplified technique the operation lasted 10 minutes and the mortality was found to be less than 4 per cent., as compared with 30 or more per cent. with other types of operation. Immediate relief was at once apparent from the operation. The size of the tumor was in direct proportion to the age of the patient. In a 12 weeks' old baby the tumor was of considerable size. No nausea or vomiting followed the shelling out of the tumor, and the child could shortly be fed per catheter, with mother's milk. By means of the fluoroscope the differentiation between the medical and the surgical cases could be definitely made. Bismuth was placed in a bottle with the mother's milk and the baby placed on its right side to allow of the peristaltic waves being seen. These were peculiarly snakelike and characteristic in appearance. When 70 per cent. of the milk passed through in 4 hours, the case was one that could be handled medically. As regards etiology, the occurrence of peristaltic waves during fetal life, probably caused the tumor, due to stimulation of the intrinsic and extrinsic nerves of the stomach.

Hypertrophic Pyloric Stenosis in Infancy.—Dr. WILLIAM D. HAGGARD of Nashville, Tenn., read this paper. Given a case of a lusty baby boy, breast fed by a healthy young mother, and the infant, two or three weeks after birth began to exhibit projectile vomiting and loss of weight, the case was almost surely one of pyloric stenosis. The operation of choice was pyloroplasty, instead of gastroenterostomy, local anesthesia being preferable. An olive-shaped tumor would be found, projecting into the pylorus, the latter being very thick, with dense mucosa. The symptoms of the condition were the projectile vomiting, emaciation, starvation stools, and diminution of urine. The child was frequently hungry, even after vomiting. Peristalsis

was visible, often being (as described by one writer) like two balls chasing each other over the abdomen. Occasionally a certain amount of food passed the pylorus, and when this was sufficient in amount, medical treatment might be employed. If there was no improvement, operation was indicated. With early diagnosis and improved technique, the mortality could be kept down to 10 per cent. In the infant, local anesthesia was more successful than in the adult, the infant having no psychic consciousness of pain or of fear. It was unwise to delay the use of surgery too long and to use it finally as a forlorn hope. Well meant but misguided efforts at too prolonged medical treatment often denied the patient any hope of recovery. The mortality of the Ramstedt operation compared with that of gastroenterostomy was stated to be as 18 to 33 per cent.

Dr. FRANK X. WALLS of Chicago said that the degree of gastric peristalsis seen in these cases gave the appearance of tumor masses the size of golf balls passing across the stomach. The disturbance was a common one in young children; it should be called "infantile pyloric stenosis." These cases often were seen after an interval following birth, in which the child was perfectly normal, and took its food in the normal way. There were normal bowel movements. Symptoms might begin in 10 days or two weeks. There was not definite atresia, because food did pass, more or less, into the gastrointestinal tract. Osler reported the case of a child that lived till 5 years of age, with pyloric stenosis. Such children suffered from insufficiency of food, marasmus, and very often died from some other condition than that of the stenosis. The cause of the disease was not definitely known. The tumor mass had been found to exist in utero, being found in the still-born. There were also cases of spasm of the pylorus, but the spasm itself did not lead to hypertrophy. The hypertrophic musculature was subject to the same stimuli as the normal muscle was.

Dr. WELLER VAN HOOK of Chicago said that the studies presented were very beautifully illustrated. As regards surgery, they had turned away from gastroenterostomy, which was, at best, but a temporizing procedure, although at times it had given brilliant results. The operation of Dr. Strauss, on the mucosa, made possible the passage of fluid, and it could be done through a small incision. Local anesthesia was a method that should be approved, but it could also be said that children stood general anesthesia remarkably well.

Dr. ISAAC ABT of Chicago said that these cases might be either medical or surgical. He remembered when medical treatment was the vogue. A number of cases then recovered functionally under various kinds of medical treatment. The mortality was, however, extremely high. The babies treated expectantly lost considerable weight, developed toxemia, and died. If the babies lost more than one-third of their weight, they were in grave danger. It was therefore a cause for thankfulness when the surgeons instituted gastroenterostomy; but even with operation there were difficulties with the baby and with the technic. In regard to statements about the use of the x-ray, he could subscribe to what Drs. Strauss and Haggard had said. It contributed nothing toward diagnosis. If the x-ray diagnosis was made by a competent technician, however, it gave almost invaluable evidence as to the functional capacity of the pylorus. It should be done in every case so that all of the facts could be ascertained. Cases had been operated upon where, after all, tumors had not been found. Some point should be remembered: babies stood long operations poorly, therefore the surgeon should operate as rapidly as possible. Attention to the closure of the wound should be careful, as an eventration had been known to occur because of hasty closure. In regard to local anesthesia, this would depend upon what local anesthetic was used. Schleich's solution had been used with disastrous results because of the morphine content. The babies went into coma. As a rule, he thought, babies stood general anesthesia well.

Dr. JOHN W. KEEFE of Providence, R. I., said he had been interested in this subject for more than 12 years. He was glad to find that Drs. Strauss and Haggard were advocating operation at the seat of the trouble. Gastrojejunostomy was never a practical

measure. If anything, Dr. Strauss did too much. A small incision could be made, the stomach and pylorus being grasped, and with the right hand the muscle could be cut, a crescentic portion being taken from each side, and a fold of omentum could be placed across and the pylorus dropped back. This did not take more than 4 minutes.

Dr. P. B. SALATICH of New Orleans asked if a Wasserman test had been made in all these cases and had Dr. Strauss saved a specimen of the section for examination under the microscope?

Dr. STRAUSS, in closing, said that he had had no occurrence of hernia, if the wound was properly closed. The use of local anesthesia would prevent shock. Pylorospasm differed from the snakelike spasm seen in this condition. In regard to cutting a piece of muscle from each side, as had been suggested, he believed it better to have complete reconstruction; the operation, as described, lasted only 10 minutes. With the other method, there might be a chance for hernia at the age of 20 or 25 years. The tumor tissue could be utilized to cover the incision.

Dr. HAGGARD, in closing, said that the local anesthetic used was novocaine, 1/10 of 1 per cent. It was surprisingly pleasing, easy, satisfactory, and efficient.

The Relation of Anomalies of the Bile Ducts and Blood-Vessels to Accidents in Biliary Surgery.—Dr. DANIEL N. EISENDRATH of Chicago presented this paper. In this matter, the text books had not kept pace with the experience gained by the surgeon. Recent articles had quoted many cases in which the hepatic ducts had been severed. The surgeon should review his anatomy of this subject and discover what he might encounter in regard to abnormalities of the ducts and arteries. Accidents to the arteries and ducts were not usually reported and thus no experience was gained by the mistakes of the surgeon. There were three reasons for such mistakes: (1) the views in regard to anatomy were out of date; (2) anomalies of the vessels were not known; (3) the normal landmarks were often obliterated. Rio Branco and Descomps, two Frenchmen, had written admirable works on this subject. According to them, the angular junction of the ducts was found in 75 per cent. of cases, but three other forms of union had been noted: (1) the parallel type, (2) the anterior spiral type, and (3) the posterior spiral type. The parallel type could be divided into: (a) short, (b) long. In regard to arteries the anomalies were divided into those in which the hepatic artery (1) crossed the hepatic duct; (2) ran parallel with the duct; (3) made a wide arch behind the duct. The cystic artery might (1) cross the hepatic artery; (2) occur in a double form; (3) cross the common duct. The gastroduodenal artery might cross the common duct. The occurrence of a double cystic artery in one case had led to an accidental hemorrhage as the second branch had been cut unwittingly, the first having been tied off. These anomalies of the vessels and ducts undoubtedly accounted for a large number of accidental hemorrhages which occurred in biliary surgery.

Dr. W. D. HAGGARD of Nashville, Tenn., said that these studies were of extreme importance. So many pathological conditions were encountered in the gall-bladder and ducts that abnormalities should be watched for. Injuries frequently occurred in the reconstruction of the common duct, and the reason was not always plain. In one gall-bladder a little bulging at the end was taken for the ampulla; it was opened and bile and stones escaped, it seemed to be among adhesions, which were wiped off and this disclosed the opening in the duodenum. Meantime the gall-bladder had been amputated. A large hepatic duct could be united to the cut ends of the hepatic branches.

Dr. E. E. MONTGOMERY of Philadelphia said that he had had one patient with the gall-bladder removed, and gallstones then formed in the stump of the cystic duct, thus demonstrating the importance of removing the duct close to the common duct and preventing the possibility of recurrence of the condition.

Dr. J. A. ATTRIDGE of Port Huron, Mich., asked if Dr. Eisendrath had ever seen a case with no gall-bladder. He had had a patient, a young man, who had symptoms of obstruction in the common duct. The stones were removed but no gall-bladder was found. Three such cases had been reported in the

literature. The young man recovered completely and was now in the army.

Dr. EISENDRATH, in closing, said that in these cases of parallel ducts, if there was a stone in the cystic duct, there might be pressure upon the common duct, giving symptoms simulating obstruction in the common duct, and the common duct might be opened in a case of that kind. There were statistics regarding absence of gall-bladder, but he did not know the figures. He had had a case of diverticulum of the gall-bladder in which there were five stones. Such cases were called cases of accessory hepatic ducts, but the stones were actually embedded in the gall-bladder itself.

Goiter in Pregnancy.—Dr. LEIGH F. WATSON of Chicago read this paper. Exophthalmic goiter in pregnancy was stated to be rare, on account of the restraining influence of the disease upon conception. Of the toxic goiters, 7 cases had been noted with exophthalmos, and nine without exophthalmos. Goiters had been supposed to be due to pregnancy, but more probably they were due to the beginning of hyperthyroidism. The subject could be divided into different parts: (1) experimental studies; (2) clinical observations; (3) treatment; (4) case records. In regard to the first division, it was found that thyroidectomized dogs produced pups with thyroids many times normal size. Pups of mothers with colloid goiters had normal thyroids. No mother with normal thyroid gave birth to goiterous pups. In sheep with athyrosis, giving of iodine restored the normal healthy condition. In regard to clinical observations, physiological enlargement of the thyroid in pregnancy was noted more in patients living in goitrous districts, but also in non-goitrous communities, more than generally supposed. In regard to treatment, that which stopped short of removing part of the hyperplastic gland would not cure the symptoms. Operation was more dangerous during pregnancy, and unless there was obstruction to breathing should not be undertaken. Organotherapy had a place in the treatment of goiter of pregnancy. Often it was necessary to administer thyroid continuously throughout pregnancy. Not infrequently it was advisable to deliver these women by cesarean section, induction of labor being too slow. Frequently the injection of quinine and urea hydrochloride into the enlarged lobe of the thyroid would relieve the patient and result in the gradual disappearance of the goiter. Cases were reported in which treatment had given gratifying results.

Dr. JAMES W. MARKOE of New York said he did not know any subject more important than that of thyroidism in pregnancy. It treated of the very vital elements of life, and covered the safety of the child afterward. Any complication of pregnancy that might occur must be met early in the period. In 1,586 cases the speaker said he had had 132 goiters, only 8 of which were toxic or true hyperthyroid types. In 28 years he had had under supervision one hundred thousand cases and had never heard of operative interference for hyperthyroidism at this time, except in one case, in which he operated personally. The woman was expecting her ninth child. She had previously had the right lobe of the thyroid removed. During this pregnancy she was really suffering from pressure of bands across the trachea. The left lobe of the thyroid was removed with complete relief of symptoms. The speaker said he did not think the pregnancy increased the symptoms of simple thyroidism. The hygienic surroundings and treatment of the patient played a large part. The patient should be put in the open air under as good conditions as possible, elimination should be attended to, and the best possible health maintained. In regard to quinine and urea injection, it was comparable to the Mayos' work with injection of boiling water, or to injection of water and carbolic acid by Ochsner. The result of this technique might be to produce edema in the tissues, to such an extent that there might be a fatal issue. This procedure should not be done at random. If operation were necessary, cesarean section might be indicated, but, with general hygienic control, the patient might be so improved that operation would not become necessary. A certain amount of shock did attend cesarean section and this should be avoided. If all these cases were more carefully watched and the symptoms noted, they would add considerably to our knowledge of this condition.

Dr. CHARLES S. MAYO of Rochester, Minn., said that this subject was very interesting to all from the point of view of the pregnant woman and from that of the thyroid. The thyroid would manufacture substances to fill the demands of the tissues for iodine. The large soft goiters meant that the thyroid was engaged in converting thyroidal iodine for the needs of the body. In some cases during pregnancy there was a wonderful relief of symptoms, but in others the women felt worse during pregnancy. If possible the pregnant woman with a goiter should be tidied through the period of pregnancy. Often after the birth of the child the goiter would have disappeared. Crile had used injections of quinine and urea in the surrounding tissues to block nerve shock from the central zone. It would seem more logical to inject the drug into the capsule of the gland itself. It would act better than boiling water, and as well as hot water. Three patients had died from injections of boiling water. The water need not be hot enough to coagulate albumin but enough to throw off the hormone of the gland more quickly. A great many cases had to be studied before one could make a definite statement as to results. Quantitative results should be studied and this body should make notes on all cases in order to determine definitely what cases should be the ones to receive any form of surgical treatment.

Dr. WATSON, in conclusion, said that 10 to 15 minims of quinine and urea hydrochloride was given at first and repeated at 1 to 5 day intervals, according to the condition of the patient. By destroying a small portion of the thyroid the danger of swelling and edema was minimized.

Secondary Tuberculous Peritonitis.—Dr. CHARLES S. MAYO read this paper, written by Dr. WM. J. MAYO (absent on military service). Tuberculous peritonitis was not a primary disease, but had its origin in local foci of infection. The focus might be (1) in the tubes in woman; (2) in the intestinal tract in woman or in man; (3) in the lymphatic glands in children. The primary focus must be the object of search. In tuberculosis, the tubes, contrary to the state in gonococcus infections, were open at their fimbriated extremities and the tuberculous process passed out into the peritoneum. Occasionally a laparotomy would cure the peritonitis, but this was in the ascitic forms of the disease, where the local focus could not be found. In the fibroplastic and adhesive types laparotomy was contraindicated. In some cases the fimbriated end of the tube became closed and a caseated mass became packed in and walled off, resulting in a "near cure." Whether the tuberculous process passed through the vagina and uterus to the tubes, or whether it gained entrance from the pelvis was an open question. Focal lesions elsewhere than the tube were difficult to locate. Often there was inflammation of the intestine and gall-bladder, but no tubercle bacilli were demonstrated in the gall-bladder, the removal of which, however, relieved the symptoms. In 47 per cent. of the cases there was said to be infection by bovine tuberculosis. This class of cases had a more favorable prognosis than that with human tuberculosis. Adhesions were often the result of mixed infections with tubercle bacilli and pyogenic bacteria; the latter, however, being shorter lived, disappeared and left the tubercle bacilli to be discovered at operation. The cases reported showed a preponderance of females over males, whereas autopsy records showed that more males than females had the disease. Pleurisy and pericarditis might be associated conditions, a polyserositis might be present or the whole abdominal cavity might be involved. The chronic proliferative form of peritonitis was never diagnosed until the abdomen was opened. This was frequently confused with the ascitic form where the cavity contained a large quantity of fluid. In local lesions, excellent results were obtained by radical surgical procedures.

Dr. R. T. MORRIS of New York thought that not enough had been said as to the follow-up treatment in surgical tuberculosis. Patients could be sent to places with 5000 feet elevation or to the sea, but should be treated so well that other people would want to get tuberculosis. Koch's O. T. should be frequently used in these cases. Dr. Morris said he had seen one case of a young woman who rather controverted the statement as to adhesive peritonitis without fluid. She was

supposed to have an abdominal tumor, malignant papilloma. As the case was apparently hopeless, they decided to let her have the comfort of Christian Science. Next year she was well, with rosy cheeks and in good health. The specimen was only then examined and tubercle bacilli were found. Another case was diagnosed as abdominal tumor but on examination of the specimen tuberculosis was found. The primary focus was never found in these cases, but under hygienic treatment the patient became perfectly strong and well.

Dr. C. A. L. REED of Cincinnati said that there was a remedy which stood in the same relation to tuberculosis that salvarsan did to syphilis. This had been used in tuberculous peritonitis with recovery in two cases. This remedy was the cyanide of copper, as used by Dr. Kogo of Japan. Results were striking in pulmonary tuberculosis. The classical symptoms subsided within 24 hours after an intravenous injection, the cough ceased, the pus disappeared from the sputum. Tuberculosis of the joints yielded in a manner equally satisfactory.

Dr. D. N. EISENDRATH of Chicago said that he felt the same way as Dr. Mayo, until four years ago in regard to removal of tuberculous tubes. He then began to doubt whether the tubes should be removed. He had a case of a young girl, 17 years, then unmarried. She had typical tuberculous tubes. A laparotomy was done and the tubes left in place. The girl married a year later and since then had had two successful pregnancies. Dr. Mayo had said that few tuberculous appendices occurred with tuberculous peritonitis, but that had not been his experience. The attacks were sometimes months apart, but often a patient would come in with tuberculous peritonitis having had the appendix removed some months previously, but evidently the specimen had not been carefully examined for tubercle bacilli. If properly examined, the appendix would show these organisms.

Dr. H. G. WETHERILL of Denver said that the experience in Colorado confirmed that of Dr. Eisenrath. Often peritonitis followed what appeared to be a primary lesion in the appendix. He agreed with Dr. Mayo that it was unwise to drain lesions in the pelvic cavity. The peritoneum had great power of resistance and could take care of itself. Drainage might produce adhesions and tuberculous fistulae in the intestine. It was better to take no risk whatever with the drainage tube.

Dr. MAYO, in conclusion, said that operation on the true adhesive type of peritonitis did no good to the individual. These people would ultimately develop tuberculosis in some other region. Tuberculosis of the appendix was more rare than other lesions, but it certainly existed. In woman the genital tract drained into the pelvis; in man this was not so, but he suffered equally from tuberculous epididymitis. In woman nature could take care of infection of the tubes, as of a caseated gland. Were this not so more women would die of tuberculosis, trying to absorb products of large caseating masses. He had had no experience with the cyanide of copper treatment. In regard to the intestine, the ileocecal valve could not be treated as a primary lesion. It should not be confused with the appendix. The types were different, and the location of the lesion should be separated. In opening the abdomen, if the patient could be kept quiet until the fever had disappeared, he would develop his own tuberculin. All patients recovering from infection developed their own antibodies if given opportunity to do so. The surgeon must learn to distinguish between the confluent lesion and the discrete lesion.

Abdominal Visceroplexy.—Dr. J. RIDDLE GOFFE of New York read this paper. Visceroplexy undoubtedly arose from careless habits of carriage of the body and from resulting lack of muscular tone. It was attended by many evils, such as localized pain and distress, interference of function, and constipation with consequent accumulation of toxins in the body and in the circulating blood. A neuropathic condition of the patient occurred as a result. Neurologists traced the course of events as arising from various toxic conditions, such as alcoholism, fright, infections, which caused circulatory changes; and then, through the action of toxins on the autonomic nerve centers, altera-

tions in the viscera came to pass. Various forms of treatment had been proposed for this disorder. The internists sought to eliminate toxins; the orthopedic men to relieve false positions; the neurologists to cure by psychic treatment. The broad-minded surgeon should consider all these means and should seek to carry the patient beyond the point where relapse might occur. In complete ptosis nothing but surgical means would be of any avail. Lantern slides were shown by Dr. Goffe, illustrating the technique of an original method of abdominal visceroplexy which had given excellent results. Four incisions were made, one above, one below, and one on each side of the umbilicus. This treatment was used in conditions where complications had occurred, such as ptosis of liver and kidneys. Many of the patients had been under previous treatment for years and were completely relieved by this operation.

Dr. C. A. L. REED of Cincinnati said that Dr. Goffe had raised important questions in this paper. There were cases in which trauma to the abdomen was the cause of visceroplexy. Heavy weights falling on the relaxed abdomen would give rise to this condition, and jars as when a heavy woman fell striking on the buttocks. Occupational conditions such as over-long standing, lifting of heavy weights, etc., were causative factors. The resources of the internist must be taxed in these cases, but where the problem was a purely mechanical one, valuable time should not be trifled away. Gymnastic and postural treatment were preoperative measures, as was the placing of the patient in the Trendelenburg position once or twice a day to relieve the mesenteric circulation. In regard to pathological changes in the ingesta, the bacterial toxins were absorbed and the blood plasma served as a receptacle for the anaphylotoxin elaborated during the condition of stasis in the mesenteric circulation. The blood from these big black veins, when put into a guinea pig would produce shock as a result of the accumulation of anaphylotoxin in the mesenteric blood.

Dr. ROSEWATER of Cleveland said that he had had wonderful results in these cases from abdominal supports properly applied. This would bring the organs into place and no operation was necessary.

Dr. REYNOLDS of Kansas City said he thought they had been much enlightened by the fluoroscopic methods in detecting positions of the ptosed organs. One was impressed with the fact that the virginal type of ptosis was a different thing from the maternal type. The type with kinks in the viscera would cause trouble. Belts no doubt had their place, but a very good point in treatment was, if possible, to get some fat on the abdomen.

Dr. AARON of Buffalo said that one point to be noted in these cases was the congenital lack of muscle tonus. A bandage might help where properly applied and the place should be studied fluoroscopically to see where the organs were. Often after the stomach had been sewn up it would be found to be as low as it was before. Some cases were medical before operation and were medical after operation.

Dr. GOFFE, in conclusion, said that he had spoken of gymnastic treatment as prophylactic, not curative. As for abdominal and kidney belts, it was often found that the kidney slipped down behind them and the patients were worse off than they were before. The kidney got strangled by being held down in malposition.

Extending the Care of Pregnancy.—Dr. IRA L. HILL of New York presented this paper. Formerly few women had attempted to place themselves in the hands of the physician early in pregnancy. This was especially true in rural communities. In the South, both white and colored women placed themselves in the care of untrained colored midwives. Attempts were now being made to put all women under prenatal supervision, regardless of whether they expected to be attended by a physician or not. In New York City zones were mapped out in which an intensive study had been organized, with house to house canvass for pregnancies, to secure early registration. All classes were included and progress was being made. Every year in the United States 15,000 women were lost in childbirth and many more were invalided. Tuberculosis alone claimed many women of the child-bearing age. In the present crisis, child conservation was becoming of more importance. With proper care there might be a

salvage of 75,000 lives. With an expenditure of 60 million dollars, a week's trained nursing for every woman could be secured. Sixty million dollars was not considered too much to spend on heavy artillery, why not let the government spend money on a national commission to conserve motherhood. Pre-maternity hospitals should be established where difficult cases could be treated. The profession would lose none of its dignity and obstetrics none of its importance if this knowledge were spread abroad. A demand would be created for higher efficiency in this art, and better obstetrics would be forthcoming.

Dr. WILMER KRUSEN of Philadelphia said that in Philadelphia the municipal authorities had been trying to have better child hygiene, but when one listened to the broad program outlined by Dr. Hill one realized that this was not a municipal, not a State problem, but an international one. The United States now held the fourteenth place among nations in regard to the mortality among mothers. They should strive to make it the first one on the list. They had been told that there were one hundred and forty-four thousand members of the medical profession in the United States, and for these men there was no work more important than this of life conservation, both of the infant and of the mother. This was an important link in the general work of conservation now being carried on.

Dr. CARSTENS of Detroit said this paper of Dr. Hill's was an excellent one. How should his suggestions be carried out? There were various ways. Better obstetrics could be taught, the students should be required to attend cases for themselves and learn the details of management of confinement. What could the doctor do? Often the patient did not come to him till the last moment, when some excited member of the family would come running and say, "Hurry up, the woman is in labor." Just here was where education of the public was needed, by means of boards of health, doctors, and nurses, so that the woman might know that, although the process was a physiological one, she should consult her physician early in order to have the right care. Education of the public called for a great deal of paraphernalia and the suggestion of Dr. Hill that Uncle Sam do the work was the right one. Every once in a while the profession should take congressmen by the neck and give them a good shake up and make them do something for the health of the community.

Dr. STEIN of Chicago said that at the Michael Reese Hospital they had made efforts to do what had been outlined. A prenatal clinic had been established twice a week, at which 30 to 70 patients attended. Blood pressures were taken; urinalyses made, and at the first visit a complete examination of the patient was recorded. The mothers were taught to have their teeth attended to, to wear abdominal support, to leave off tight strings, etc., and the willingness of the patients to be taken care of was gratifying.

Dr. HILL said that midwives, under this scheme, had been brought under proper supervision. Another interesting fact was that the tax levied to support the Bureau of Child Hygiene in the Department of Labor amounted to \$200,000 and represented a tax of one-third of one cent per year on each inhabitant, so that it could be seen that the Government could easily raise more money without working any injustice to the community.

Uterine Inertia.—Dr. PAUL TITUS of Pittsburgh presented this communication. It was doubtful whether inertia could be classed properly as "primary" or "secondary." The question of time entered into the estimate of the matter. A primipara with an average sized baby, and a multipara with a small baby, might have labor of equal length. It was not known why 280 days should elapse before labor occurred. This time did not seem to have direct bearing on fetal life. When labor was artificially induced after premature rupture of the sac there was always more or less inertia. This might be secondary to some primary condition. True inertia was probably some inherent fault in uterine muscles tone and secondary inertia was probably exhaustion from exertion against some force encountered. In the two states, treatment was different. In inertia little was to be done, but with exhaustion, due to contracted pelvis, face presentation, etc., there were certain forms of treatment. Individuals

below par faced the strain of labor poorly, had little patience, and made a great demonstration, which, unless the physician was sure of his ground, would constitute a complication. Dry labors were supposed to be troublesome, but some of these women did have strong labor pains, and those with late rupture of the sac often did not, so that inertia was a condition of itself and not dependent upon other phenomena. In all cases of inertia, rectal examination, rather than vaginal, was recommended, in order to avoid infection. At no stage of labor should pituitary extract be used, unless after the expulsion of the placenta. In conclusion it might be said that treatment in inertia was expectant, and in exhaustion prophylactic. Treatment of exhaustion in the first stage of labor was by uterine stimulants; in the second stage, by multiple incisions of the cervix, by forceps, or by vaginal cesarean section. Retention of placental material, with or without hourglass contraction of the uterus, might occur with this condition.

Dr. R. W. HOLMES of Chicago said that the views he had held were not always in consensus with the views of the profession. The time honored classification was that of primary and secondary inertia. The secondary inertia was due to exhaustion. The primary inertia might be due to faulty involution. In some cases there was abnormality of the muscles. After repeated pregnancies the muscles lost tone. Primary inertia was extremely rare, and very few men really saw the condition. It was not the fault of the uterus, but of the contributory factors. The inertia was the effect and not the cause. There were various causes for this, such as malpositions causing abnormally weak contractions; contracted pelvis with aberrant pains; fibroid conditions, prolapsed ovaries or kidneys. These conditions meant that the presenting part could not come down. A woman might go a week with abnormal contractions and then finally labor might be quite sudden. In regard to premature rupture of the membrane, this was of little significance, but what had caused the rupture was the important thing. This cause was malposition. In Chicago the doctrine of the obstetrical misfit was not taught. It was often found that tuberculous women had extremely normal labors. The uterine muscles stayed strong until the end. The recognition and treatment of the malposition was the important point. The woman should be kept quiet, allowed to rest. The family should be kept quiet. In time, when ready, the uterus would contract. Repeated vaginal examination was a menace to the woman. The administration of pituitrin was an egregious crime. In primary atony, with or without rupture of the membrane, the point to remember was to keep hands off, and it would be rarely necessary to have operative interference. Cesarean section might have to be done in obstruction, but with primary atony never.

Dr. TITUS, in closing, said that they had all seen cases start off with force and develop into secondary inertia. These were really exhaustion. Difference in treatment of inertia and exhaustion depended upon the underlying cause. With pendulous abdomen or malposition inertia was a secondary condition. Rupture of the membrane was not due to failure of engagement of the presenting part. Rupture often occurred when the presenting part was nicely engaged. This was seen in primiparæ. Often inertia was secondary to early rupture of the membrane.

The Use and Abuse of Pituitary Solution.—Dr. GEORGE W. KOSMAK of New York presented this subject. No addition to the obstetrical armamentarium had produced so much discussion as pituitary extract. In experimental animals the drug caused marked uterine contractions. The therapeutic use of the drug was based on this fact. It increased by leaps and bounds. Most preparations were made from the posterior lobe of the gland, but some of entire gland. The reliability of some preparations was greater than that of others and manufacturers had not standardized the hypophyseal extracts. This should be done. Great exploitation of the drug was attempted by high-sounding advertisements and its use was represented to be free from dangerous consequences. These statements should be modified. As with all endocrine preparations there was great variation of the drug. Its obstetrical use should be strictly limited to cases of inertia where no obstruction existed. If used in doubtful cases to stimulate

labor, laceration of the cervix, or rupture of the uterus might result. Unless the indications were specific, very grave dangers attended the use of the drug. Pituitrin might be used where the head was engaged, in order to stimulate the head to a lower level. Forceps was to be used when the head was not engaged. In checking hemorrhage, the results were only temporary. Dr. Kasmak said that he was less pessimistic about the drug than he was about getting the profession to use it properly. The drug had a certain limited use and should be tested in small doses of one-third of 1 c.c. More could be given if found safe. In menorrhagia of young girls and in fibroid cases of older women there were indications for the use of the drug.

Dr. J. B. DE LEE of Chicago said that he was one of the first to oppose the use of pituitary extract in labor. Further experience had confirmed the opinion. Rupture of the uterus and laceration of the cervix had followed improper use of the drug. Asphyxia of the new born had been caused and the endocrinal relationships of the fetus had been disturbed. As to the use of the drug in cases of cesarean section, it should not be given after the sutures were put in, as the sudden contraction might tear the sutures out, and peritonitis follow. In true primary inertia with or without rupture of the waters pituitrin might do good.

Dr. J. L. BUBIS of Cleveland said that during the past six years he had noted bad effects from large doses of pituitrin before the child was born. He had used very small doses. In post partem hemorrhage no drug would act so quickly. As a galactagogue it was not satisfactory. In retention of urine it did not give good results. Half an ounce of sterile glycerin introduced into the bladder did away with the use of the catheter.

Dr. LITZENBERGER of Minneapolis said that he was glad to hear Dr. Kosmak sound this warning. Rupture of the uterus had occurred in many cases. Another complication was hemorrhage of the brain of the fetus. This remedy was passing through the stages through which all new remedies passed, before finding their level: (1) neglect; (2) promiscuous use by everyone; (3) exploitation; (4) stage of reaction; (5) stage of rehabilitation. The reaction often went further than it should and the climb back to favor was often slow. The drug finally found its level of usefulness. Pituitary extract had now reached the fourth stage. It should never be given before the cervix was fully dilated, except in exceptional cases.

Dr. BACON of Chicago said that there was the medico-legal aspect to be considered. In one case a practitioner was blamed because he did not use the drug, for a forceps operation resulted unfortunately. That case was easily defended, but cases in which the drug was used and in which the baby was born dead, or in which there were serious results, could not be easily defended.

Dr. W. P. MANTON of Detroit said that he endorsed the remarks of Dr. Kosmak. He taught his students to avoid the drug. He hoped in this case that the stage of rehabilitation would never arrive.

Pus in the Female Pelvis.—Dr. JOHN Y. BROWN of St. Louis read this paper. He referred to the great controversy formerly raised by the views of Tait on pus tubes. He showed that many cases ended in complete recovery. These were not the cases seen by the specialist, and patients often went on to chronic invalidism. This matter must be studied on both sides. Peritonitis following salpingitis was of rare occurrence and many cases doubtless recovered without operation. Where acute exacerbations occurred it was wiser to defer operation. Simpson recommended putting the patients to bed for three weeks without operation. It was hard for the writer to believe that multiple abscesses could yield to this conservative treatment. Incomplete work was responsible for immense amount of suffering. It would be unnecessary to discuss the technical details of this condition because each case was a law unto itself and the surgeon must work out the individual problem. The question of drainage was highly important. The coffer dam drain was of value. The intestines were lifted out of the cul-de-sac and a gauze roll inserted, the end of the gauze being brought out through a thin rubber tube. Conclusions were that many cases might recover without operation; 98 per cent. of the cases became quiescent; operative work

should not be undertaken when in the acute stage; when undertaken, operative work should be radical in the extreme.

Rectal Surgery for Pelvic Abscess.—Dr. HARRY P. RITCHIE of St. Paul, Minn., read this paper. He had found this operative route very efficient in certain cases of peritonitis where vaginal section was unsuitable. In peritonitis resulting from appendicitis early intervention was called for and where lack of hospital care was present pelvic abscess might occur and necessitate drainage. Often a secondary operation became imperative, and in these cases so disturbing to the patient and to the surgeon it was often far easier to drain by the rectal route. The points of operation were dilation of the sphincter, the incision and the insertion of the rubber tube. Repeated observations were necessary as changes might occur in a few hours. In certain specially indicated cases this operation would solve the problem.

Dr. CARSTENS of Detroit said that in appendicitis an opening in the right inguinal region was much easier. (One should have a little more faith in nature; nature would wall off the abscess and plaster the omentum and there would be no trouble in draining it. In exceptional cases only, where the abscess developed between the pelvis and bladder, this operation might be indicated. Ninety-nine per cent of cases would recover if let alone; if, later, they showed symptoms, the necessary steps could be taken. The cofferdam drain was 20 years behind the times. He could not see why one did not drain downward and open the cul-de-sac, which gave natural drainage into the vagina.)

Dr. E. MONTGOMERY of Philadelphia said that patients suffering with gonorrheal infections with masses in the pelvis often declined operation; these were apt to recover and later give birth to children. Some recovered in spite of the methods of treatment formerly considered necessary. Surgical intervention at a late stage gave better results, for then the micro-organism had died and the pus had become sterile. Sometimes vaginal section was necessary to relieve acute symptoms by lessening the accumulation. He quite agreed that there should not be drainage through the abdominal wall, if avoidable, on account of the possibility of late hernia. Vaginal drainage was infinitely preferable.

Dr. GEORGE N. THOMAS of El Paso, Tex., said that he felt the question of nationality and type of patient entered into this matter of pelvic infection. At El Paso the patients were of a low class, mostly of the Mexican race, and altogether of a different type from the average American patient. Neisser infection was very common, probably all the infections being due to this type. He thought the infections in better classes of women occurred from undue coitus and were infections through the broad ligament. These went deeper and tended downward into the cul-de-sac. There was a stage where the temperature ran normal, but if there was a rise of temperature and marked bulging of the tube, surgical procedure was indicated. Vaginal drainage was best where there was a bulging into the cul-de-sac.

Dr. M. PFEIFFENBERGER of Alton, Ill., said that in an experience of 16 years he had seen results of both conservative and of radical procedures. A condition of "nervous wreck" frequently followed panhysterectomy. With proper drainage mortality could be reduced to a minimum. In regard to incision from the rectum, it was possible to leave one abscess entirely. There might be inflammation in both tubes and one would be left. In appendix conditions one could drain through the pelvic incision. The abdominal right hand drainage gave the safest and best results.

Dr. H. G. WETHERILL of Denver said it was hard to believe that the nationality of the patient could make much difference in the pathological process. It made little difference whether the infection were Neisser or not so nice. Abdominal operations should not be done in the acute stage of these infections. These things were more or less self-limited and frequently took care of themselves so that the patients might later even bear children. The infection was limited by the biological life of the organism involved. In the light infections where considerable degree of sterilization had taken place no drainage was necessary. The thick cheesy

material could be wiped out and the wound closed with good results. Drainage, when necessary, should be made through the right pelvic canal.

Dr. B. SALATICI of New Orleans said that he did not use vaginal drainage any more. He did not operate until the fourth or fifth week. The pendulum in the treatment of these cases was now swinging the other way in the direction of conservatism.

Dr. R. T. MORRIS of New York said that in these inflammatory processes of the pelvis there was a fight between the bacterial invaders and the patient. The best way of controlling the bacterial process must be considered. Nature in time walled off the area of infection. Morphine was the drug that aided most in the development of protective resources, but, at the same time, it was one which induced habit, so that the surgeon was between Scylla and Charybdis. When it was necessary to do something quickly for the patient, opium was the safest drug to use. One grain on the tongue would be sufficient. Alonzo Clark had said, "don't measure the amount of opium, measure the respirations of the patient." This was a maxim that should not be forgotten. In the chronic stage, there was much to be done in the way of conservatism and in saving the cervix. The fibriæ at the end of the tube could be saved and to make a closure of the tube. In one case where a matter of a million dollars hung upon the possibility of the birth of a male child the closure of the tube was effected by doubling up the end. The patient had subsequently given birth to a boy. There was no use in removing the uterus or the ovary. A lot of conservative work could be done. This was the time to use deliberate judgment.

Dr. BROWN, in conclusion, said that his paper dealt with descending inflammation of the pelvis, not that above the pelvic brim. The rule in ascending infection was to operate early. It was only in quiescent cases that late operation was of use. Ovary cases were a law unto themselves. In regard to drainage from above, he agreed that many cases could be closed up without drainage at all, but the coffer dam drain was used to prevent the small intestines falling back into the pelvis.

Dr. RITCHIE, in conclusion, said that the rectal operation was not offered as a substitute one; it was only justifiable under certain conditions. When the appendix was already out and when another laparotomy would appear to be advisable, this operation was a very good thing to do. Its application was only occasional, but, as an easy way out of a difficult situation, it had a distinct place.

Parotitis Following Induced Abortion in a Case of Pernicious Vomiting in Pregnancy.—Dr. W. P. MANTON of Detroit reported this case. The patient, 23 years of age, a primipara, had chronic pernicious vomiting. The uterus was emptied and shortly after the patient became delirious. The left parotid gland became inflamed and contained a large amount of pus. Altogether four abscesses were incised and drained. The meninges later became involved, then the nose, mouth, and finally the eyes became filled with purulent material. After 33 days of intense suffering the patient succumbed. This was evidently a case of septic infection. These cases had in early times been ascribed to the work of demons, later to the chastisement of Providence, and later still to an equally unknown quantity—"reflex phenomena." A considerable number of these instances had been reported, many following operations such as amputation of the thyroid, removal of hemorrhoids, etc. Specific parotitis was supposed to have some connection with the pelvic organs. The usual organism was a staphylococcus, but it was occasionally a streptococcus. One point to be noted was that the parotid, alone of the salivary glands, was connected with the lymphatic glands and infections might be communicated through Stensen's duct. The mouth contained flora, usually harmless, but which, after operation and lowered resistance, might become virulent. Perhaps this was caused by drying of the secretions during anesthesia. The infections in these cases might then be considered oral, rather than pelvic in origin.

Dr. E. E. MONTGOMERY of Philadelphia said that he had seen cases of parotid infection following various operative procedures. These cases were due to neglect

in technique or to defective secretion. The organism no doubt entered from the mouth, passed into the gland, and into the lymphatic circulation.

Dr. MARTIN E. KLINGER of Garrett, Ind., said he had a patient, 32 years of age, with right-sided lobar pneumonia. On the sixth day of the disease she aborted. On the 12th day a right-sided parotitis occurred. It did not form pus. A week later there was a right-sided hepatitis which did not form pus. On the 35th day there was an appendix abscess. The appendix was removed and the abscess drained. Finally on the 50th day a right-sided empyema occurred. These conditions appeared a chain of events in a generalized infective process.

Dr. S. E. TRACY of Philadelphia said he had seen parotitis following operation which had cleared up promptly. He was inclined to think it was an oral infection. He believed in these cases that more attention should be paid to the patient's mouth before operation. Soreness at the angle of the jaw might be something more serious than parotitis. In one patient who had complained of this symptom 8 days post operatively there was a fully developed tetanus. This warning should be kept in mind.

Dr. MANTON, in conclusion, said that this condition following emptying of the uterus was rare. Even up to the present time surgeons were apt to claim that these cases of infection of the parotid gland were due to sympathetic phenomena. He was not a believer in sympathy of that kind. Surgeons should be more on the look-out for infections which might occur orally in the first place and then be transmitted by way of Stensen's duct.

(To be continued.)

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

HOW TO ENLIGHTEN OUR CHILDREN. By MARY SCHARLIEB, M.D., M.S. 192 pages. Price, \$1.00. Published by Fleming H. Revell Company, New York.

THE SURGICAL CLINICS OF CHICAGO. April, 1918. Vol. 11, No. 2. 435 pages. Illustrated. Price, \$10.00 per year. Published bi-monthly by W. B. Saunders Company, Philadelphia and London.

INTERPRETATION OF DENTAL AND MAXILLARY ROENTGENOGRAMS. By ROBERT H. IVY, M.D., D.D.S. 146 pages. Illustrated. Price, \$2.50. Published by C. V. Mosby Company, St. Louis.

ORAL SEPSIS IN ITS RELATIONSHIP TO SYSTEMIC DISEASE. By WILLIAM W. DUKE, M.D., Ph.B. 124 pages. Illustrated. Price, \$2.50. Published by C. V. Mosby Company, St. Louis.

SYPHILIS AND PUBLIC HEALTH. By EDWARD B. VEDDER, A.M., M.D. 315 pages. Price, \$2.25. Published by Lea & Febiger, Philadelphia and New York.

THE TECHNIQUE OF PSYCHOANALYSIS. By SMITH ELY JELLIFFE, M.D. 163 pages. Price, \$1.50. Published by Nervous and Mental Disease Publishing Company, New York and Washington, D. C.

X-RAY ATLAS OF THE SKULL. By A. RUSSELL GREEN, M.B., B.S. (Lond.), M.R.C.S. (Eng.). 27 pages. Illustrated. Price, \$3.50. Published by Longmans, Green & Co., London.

HEALTH SURVEY OF MIDDLETOWN, CONN. By DAVID GREENSBURG and IRA D. JOEL. 73 pages. Illustrated. Published by Department of Public Health, Yale School of Medicine.

SEVENTEENTH ANNUAL REPORT OF THE NEW YORK STATE HOSPITAL FOR THE CARE OF CRIPPLED AND DEFORMED CHILDREN. For the year ending June 30, 1917. 40 pages. Illustrated. Published by J. B. Lyon Company, Printers, Albany.

BLESSURES DE LA MOELLE ET DE LA QUEUE DE CHEVAL. Par G. ROUSSY et J. LHERMITTE. 202 pages. Illustrated. Price, 4 francs. Published by Masson et Cie., Editeurs, 120 Boulevard Saint-Germain, Paris.

THE ORIGIN AND ORGANIZATION OF THE DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK.

By STEPHEN SMITH, M.D., LL.D.,
NEW YORK.

BAAS, the eminent historian of medicine, regards epochs as the essential features of history. He says: "An acquaintance with the views and knowledge of epochs already submerged in the shoreless ocean of time frees the mind from the fetters and currents of the day, with its often oppressive restraints, widens the horizon for a glance into the past, and insight into the present of human activities, deepens the view for a comprehension of the ideas which guided the earlier and more recent physicians, and gives, on the other hand, to our daily professional labor a high consecration."

The organization of the Metropolitan Board of Health in 1866, which is the present Department of Health of New York City, created an epoch in the history of preventive medicine. The recent investigation of that department shows that an "acquaintance with the views and knowledge" of that great epoch are already submerged in the shoreless ocean of time. It may, perhaps, prove instructive and useful to recall some of the incidents of the origin of that department which illustrate the ideas that guided the earlier and more recent physicians.

Prior to 1866, New York City had neither health laws nor administration of the slightest value. Its health ordinances were mere "scraps of paper," and its administrators were politicians of the lowest grade. Its Board of Health was the Aldermen called and commissioned by the Mayor to act in that capacity. Of the efficiency of that board we have the testimony of Mayor Fernando Wood, who was urged to call the Aldermen together as a Board of Health during an epidemic of cholera, but declined, stating that they would be more dangerous to the city than the epidemic. The "city inspector," a nondescript official, was the only public officer who exercised any health powers, and those consisted chiefly in the appointment of "health wardens," who were usually saloon keepers. The qualifications of these officials was put to the test by a legislative committee appointed to investigate the sanitary condition of the city. One was asked the meaning of the word "hygiene," and he replied, "the mist that rises from standing water." Another gave as the remedy for smallpox, burning sulphur in the patient's room. A third, asked what

he did when called to visit a case of contagious disease, said he never entered the house but gave directions from the street.

The unsanitary condition of the city prior to 1866 cannot be described so that an audience of to-day can fully appreciate the reality. Nuisances dangerous to life and detrimental to health existed everywhere. Large areas were undrained, giving rise to miasmatic fevers in the autumn; the cobblestone-paved streets were lined and littered with garbage; small butcher shops were in every section, requiring herds of cattle, sheep and hogs to be driven through the streets; the scavenger's cart, loaded with domestic filth, filled the night air with suffocating odors; the river fronts were lined with fat-melting and other offensive industries. Life in the streets, now made perilous by the automobile, was then even more endangered by stray cattle made furious by the hooting, chasing mob. It was not an uncommon event that the Texan steer in his mad career impaled a child or feeble pedestrian on his long, pointed horns.

The enormous tenement population lived in a nomadic style, and upward of 18,000 persons (Troglydites) lived in cellars, under every possible unsanitary condition. As a result of these conditions New York was rated as one of the most unhealthy cities of the world, its mortality rate varying from 35 to 45 per thousand population. Contagious diseases of every kind found here a congenial culture bed where their germs multiplied without "let or hindrance." Smallpox was epidemic every fifth year, miasmatic fevers appeared with "their usual severity," as the record states, every autumn; typhus fever came with the immigrants, and scourged the tenement-house and underground population; cholera reached the city at intervals and decimated the people with all the malignity it exhibited in the Ganges; the domestic pestilences, diphtheria, scarlet fever, measles, were always present.

It is surprising now to recall the entire indifference of the people of every class to the perilous conditions under which they lived. A woman living in a cellar where the only light was a candle, and her three children were tuberculous, made the universal reply when a dispensary physician remonstrated with her for living in a cellar: "I have always lived here. This is my home. I am contented and happy. Why should I leave my home?" The wealthy and intelligent residents who were appealed to in aid of efforts to secure reforms through legislation made, in effect, the reply that this condition had always existed, and refused to attempt reforms.

The climax was reached in the early sixties. I

was in charge of a typhus fever hospital, and noticed that a large number of patients came from one tenement house. On visiting it, I found a true "fever nest." The house was in a most unsanitary condition, and was crowded with immigrant families suffering from typhus, but without furniture or care of a janitor. In my efforts to have the house vacated, cleansed, and closed by the police, it was found that there was no law, ordinance, nor even authority, which could be employed to abate this nuisance dangerous to life and detrimental to health.

These facts were reported to the Citizens' Association, a powerful body recently organized to effect reforms in the city government, with Mr. Peter Cooper as president, and a membership of prominent citizens. This association adopted the suggestion of Mr. Cooper that it should undertake to secure a code of health laws. Two committees were established, one of hygiene and the other of law, and prominent members of the medical and legal professions were appointed on them respectively.

The joint committee first made a careful examination of existing conditions and the causes of failure of efforts hitherto to secure legislation. The conclusion was that there was no public interest adequate to sustain the movement, and that the first step to be taken by the association was the creation of a public sentiment which would support the proposed effort of the association.

This was the advice of Mr. Dorman B. Eaton, secretary of the law committee, who had recently, while in England, made a careful study of its public health service. The great success of its sanitary laws was attributed to the care of the authorities to educate the people by the wide circulation of the reports of the registrar general and leaflets written in plain language. By this means the people became so interested in sanitary measures that they even attended political meetings and greatly disturbed candidates for office by questioning them as to their position on current popular public-health subjects. It is stated that a prominent candidate was so disconcerted by these questions that he cried out, "*Sanitas sanitatum omnia sanitas.*"

Mr. Eaton was impressed with the great importance of a campaign of education as the foundation of the association's efforts, and he recommended its undertaking a complete and exhaustive sanitary survey of the city by medical inspectors. Accordingly, the association authorized the committee on hygiene to make such survey, and promised to finance the work. The committee appointed a sub-committee, of which I was chairman, to conduct the survey. The details of the work were very carefully prepared by the committee, and the summer of 1864 was devoted to its execution.

We divided the city into thirty-one inspection districts, and selected a physician for each, the salary being \$30 per month. At the close of the inspection, which was completed in about four months, the committee presented to the association seventeen folio volumes of reports which embodied accurate statements, with drawings, of the grounds, tenements, and their occupants, industries, etc.

This survey has been pronounced by high authority as the most perfect sanitary investigation of a municipality on record. At its conclusion the principal facts recorded were embodied in a volume by Dr. Elisha Harris of the committee, and was widely circulated among the people of the city and State, with the effect that a powerful public sentiment was created which subsequently sustained the efforts of the association.

The association authorized the two committees to prepare a bill, based on this survey, to be introduced into the Legislature. In consultation it was decided to create a metropolitan health district, coextensive with the metropolitan police district, in order to place the jurisdiction of the department in the State government rather than in the city government, then under the Tweed regime. The committee on hygiene were requested to make the first draft of the bill, and that duty was assigned to its sub-committee. On its completion it was referred to the committee on law, and perfected in its present form.

The association deputed Mr. Eaton and myself to appear at the hearing on the bill before a joint committee of the two houses of the Legislature, Senator Andrew D. White being chairman. The city inspector and his health wardens were present. The evidence which we presented of the dangerous unsanitary condition of the city and the homes of the tenement-house classes, as revealed by the survey recently made by physicians, was so overwhelming that after a few vain efforts to refute our reports the city inspector and his following withdrew.

The bill passed the Legislature of 1866, with an appropriation of \$50,000, and the board organized in March of that year. Several of the early sessions of the board were largely devoted to an informal consideration of the policies which the board should pursue. The field of future operations and the methods of procedure were new to the members, but they were of a receptive mind. In these discussions Mr. Eaton, who had been a close student of the administration of the public health laws of England, then the most advanced of any country, took a leading part.

He stated that there was a feature of the new law which the board should understand at the beginning of its work, for it was its most important feature, but was certain to be attacked in the courts. While the law embodied all the best features of English health laws, it had in addition a provision which rendered it unique, indeed—an anomaly in legislation. Under that provision no court or other official body could by any process interfere with the action of the Board of Health in abating any matter or thing declared under its rules to be a nuisance "dangerous to life and detrimental to health."

As he predicted, the constitutionality of the law was contested in the courts, and was finally decided by the Court of Appeals in favor of its constitutionality by a majority of one.

The value of that provision was put to the test when the board attempted to abate nuisances hoary with age and protected by political and vested interests, like the booths around Washington Market, the offensive trades and slaughter houses. They

resisted the orders of the board until it enforced them by abating them on its own initiative and charged the expense to the owners. The parties applied to the courts, but no protection was given. In one night Washington Market was made clean for all time by the removal of its booths to the public yard. An offensive fat-melting establishment on the riverside that had resisted every previous effort to abate it was summarily removed and the owner compelled to pay the costs of removal. These few exhibitions of the power of the board taught the people an invaluable lesson. Upward of fifty suits against the board pending in the courts were withdrawn, and thereafter its orders were executed with reasonable promptness.

Mr. Eaton was so impressed in England with the importance of having a strong public sentiment to sustain the initiation and enforcement of health laws that he advocated the education of the people in the practice of sanitation by the publication of the current work of the board in familiar form for the common reader. Accordingly, Dr. Elisha Harris, the registrar, a man eminently qualified for that duty, issued a circular regularly explaining the current operations of the board. It proved a surprise that from its first publication the circular was in great demand, and that it acquired a national reputation. It has been stated that it led to the organization of large numbers of health boards.

It would prove very instructive if the Health Department would, in its next publication, collect the interesting letters which this investigation has elicited from the health authorities of different localities protesting against the threatened disorganization of the department and acknowledging their constant indebtedness to its advanced teachings in the science and art of civic sanitation.

Another feature of popular education introduced by Mr. Eaton was the policy of requiring the owner of the matter or thing declared to be a nuisance to abate it, though the board had that power. He regarded the act of abatement as educational, and it proved true. In numberless instances, landlords who had been compelled to abate a nuisance afterward voluntarily performed similar acts, and even reported them to the board to prove their independence of its orders.

The plan of specializing its work for the purpose of securing expert inspectors in every branch was early undertaken, and has been carried to a high state of perfection in these later years. The engineers, Mr. Worthen and General Viele, planned and executed a system of deep drainage of the water courses to the rivers which forever banished miasmatic diseases from the list of what were known as indigenous affections. Prof. Charles F. Chandler of the Chemical Laboratory made an investigation of the "gas nuisance," and determined the remedial measures which relieved the citizens of that perpetual source of ill health and discomfort.

A striking example of the value of specializing to secure expert work was the creation of a corps of vaccinators, whose duty was to secure the vaccination of every new-born child. Previously, smallpox was epidemic in this city every five years, the daily number of cases often amounting to

three or four hundred. From the date of the separate corps of vaccinators, now nearly fifty years, there has been no epidemic of smallpox, and only occasional cases of that disease, which were for the most part brought here from the neighborhood.

The organization of a disinfecting service of skilled workers had the effect of controlling the spread of infectious epidemics. An epidemic of cholera began in this city soon after the organization of the board, attended with the usual flight of the wealthy classes to the country. So immediate and effectual was the work of the disinfecting corps when a case of cholera was reported that no two cases occurred in the same place, and the epidemic soon disappeared and has never gained a foothold since.

The cultivation of serotherapy by the department in the treatment of infectious diseases has already stricken diphtheria from the catalog of dangerous affections, and is destined, if persevered in, to render innocuous the whole brood of domestic pestilences.

The supreme test of the efficiency of a department of the city government must be the extent of its accomplishment of the purposes for which it was created. Judged by that standard, the Department of Health of this city stands unchallenged by its intelligent citizens and the admission of the health authorities of this continent in the first position. It was created to protect and promote the public health. The mortality and morbidity rates of 1866, compared with those of 1918, abundantly sustain the public judgment that it has amply fulfilled its mission. That comparison shows that the death rate has fallen from 38 to 40 to 12 to 15 per 1,000 population; that is, 23 persons in every 1,000 population are now annually saved who would have died if the death rate were the same now as it was prior to the year 1866, when the Health Department was organized as the Metropolitan Board of Health. Carried to its logical conclusion it follows that of its present population of 5,000,000 there is an annual saving of 115,000 lives. From a city ranked as among the most unhealthy of the great capitals of the world in 1866, New York contests the position of those cities claiming to be the healthiest.

Whatever may have been the motives of those who instigated the present investigation, the Health Department ought to be benefited, for it has placed on the public records the estimation in which it is held by the highest authorities, and will lead to the correction of defects in its present methods of administration. It may, indeed, prove the desirability and utility of requiring every incoming municipal administration to institute among its first acts an official inquiry into the operations of each department to determine its efficiency in accomplishing the purposes for which it was created. It is certainly gratifying to notice that the newly appointed commissioner is inspired by the same high ideals which governed the founders of the department, who, in 1866, laid its foundations so wisely that after a half century it stands unrivaled in accomplishing the objects for which it was created.

WHAT THE GENERAL PRACTITIONER SHOULD KNOW ABOUT ACUTE GONORRHEA IN THE MALE.*

By ABR. L. WOLBARST, M.D.,

NEW YORK.

CYSTOSCOPIST, BETH ISRAEL HOSPITAL; CONSULTING UROLOGIST, CENTRAL ISLIP AND MANHATTAN STATE HOSPITALS; ATTENDING GENITOURINARY SURGEON, WEST SIDE GERMAN DISPENSARY AND HOSPITAL.

NOTWITHSTANDING the heroic efforts being made by the medical authorities in the army and navy, it must be evident that one of the great after-the-war problems will be the control and management of the venereal diseases, not the least among which must be considered gonorrhea. It is the purpose of this paper to consider the subject of acute gonorrhea in the male, from the aspect of the general practitioner, who is usually first consulted by the patient on the outbreak of this infection.

It is well to take stock, so to speak, of what we know of this perplexing subject of acute gonorrhea, in so far as it applies to the general practitioner, so that we may determine as briefly as possible what he should know about the disease and its treatment, and thereby come to a full realization of his capacities and his limitations.

Above all, he must know that gonorrhea is a disease which cannot always be cured by a syringe and a bottle of medicine. He has been accustomed to consider the infection as a purely local one, usually involving the anterior portion of the urethra, and ignoring entirely the fact that most if not all gonococcus infections of the urethra sooner or later involve the posterior portion of the canal as well as the anterior. If he will but bear this in mind he will be spared many disappointments from the standpoint of diagnosis and therapy.

Secondly, he should remember that an attack of gonorrhea, uncomplicated and properly treated, should be thoroughly cured within six to ten weeks. Therefore when an acute infection of the urethra has dragged along for eight, ten, or twelve weeks, with the end not yet in sight, there is something wrong somewhere, either with the diagnosis or the treatment, and the general practitioner has come to the end of his tether. He should know that he requires assistance.

Undoubtedly some cases remain uncured because of improper treatment; some because of insufficient treatment; but most cases, I believe, drag along because of excessive treatment. The prudent physician will often stop his local treatment for a time and watch the result; and he will be surprised at the sudden improvement in his patient.

On the other hand, a change in the treatment may be required. The injection solution may be too strong or too weak; it may possibly irritate the canal. Substituting another preparation for the one that has been used will often convert an angry, uncontrollable infection into a most docile and responsive one.

If these changes do not bring about the desired result there must be something wrong with the diagnosis. Probably the posterior urethra is involved; this must be determined. Possibly there is a more or less well defined stricture in the ure-

thra, a relic of some previous battle with the gonococcus; this must be determined and treated. There may be a glandular focus which is not reached by local medication; this must be found and the appropriate treatment administered.

The point I wish to make is that an uncomplicated case of gonorrhea has a well defined period of time in which it ought to be cured, and if this period is unduly delayed every effort must be made to seek the cause and apply the suitable remedy; and it is but justice to himself and to the patient for the practitioner to secure assistance as soon as it becomes evident that control of the infection is slipping from him.

Another important thing for him to know is that we have no specific remedy for gonorrhea. In a multiplicity of remedies there can be no specific. We have excellent remedies that will cure gonorrhea, but while any one of them might be surprisingly successful in nine cases, it may fail utterly in the tenth. We must therefore become acquainted with all of them; we must learn their respective virtues and faults. We must learn from experience when they may be used and when it is better not to use them; in what strengths and in what circumstances they are apt to produce the best results, and vice versa.

Without going into details as to their respective merits and faults, it must be recognized that our sheet anchor in the treatment of acute gonorrhea lies in three well-known preparations—argyrol, protargol, and permanganate of potassium—and if a practitioner finds that he cannot cure his case under the intelligent use of these three remedies, within a reasonable period of time, he must be convinced without further delay that the case calls for treatment at more experienced hands.

It is difficult to say how these remedies should be used; just as difficult as it would be to teach heart and lung sounds from text books. They must be learned only through actual experience. Experts differ as to their employment; some prefer strong solutions, others prefer them weak; some repeat injections three or four times daily, others consider this too often and give but one treatment per day.

All men do not get the same results with any particular remedy. It is almost impossible to sift the wheat from the chaff in all that has been written about the subject. Out of the mass of bewildering contradictions and diversity of opinions one must learn for himself how to use these remedies. He must learn for himself whether protargol is better in acute gonorrhea in $\frac{1}{2}$ per cent. or 2 per cent. strengths; whether argyrol is more effective in a 5 per cent. solution or a 10 or 15 per cent. strength. No one can give him this information. My own preference is for weak solutions at all times; I believe the inflamed urethra resents the injection of strong irritant solutions; on the other hand, a colleague whose opinions I respect highly, prefers strong solutions, often repeated. This is a matter that cannot be debated or arbitrated; the personal equation is a most important factor in determining a man's views. Every man must determine for himself what is best to be done and what will give him the best results.

Not for one moment should the practitioner for-

*Chronic gonorrhea in the male will be considered in a subsequent paper.

get that each patient must be studied and treated as a distinct individual, subject to peculiar idiosyncrasies and reactions. While one patient may respond beautifully to a certain local injection, another patient may be irritated and traumatized by a solution half as strong. The personal equation never must be lost sight of. One man's meat is another's poison. There can be no fixed rule for every case. Each case must be studied and treated according to its own merits. We shall therefore find that we must adjust our treatment according to the idiosyncrasies of our patients; and the practitioner will do well to study these idiosyncrasies, for the successful practitioner will be the one who can most quickly recognize them and adjust his treatment accordingly.

Another important fact worth remembering is that gonorrhea requires the personal attention of the physician to no less a degree than any other human ailment. What practitioner would think of prescribing for a patient with pneumonia on his first visit, and letting him go for a week without seeing him? Yet this is exactly what he does in his management of acute gonorrhea. He generally prescribes an injection, possibly an internal alkaline solution in addition, and tells the patient to come back in a week. The practitioner should know that this is bad practice; the patient should be seen every day, at least for two or three weeks, if this is at all possible, and the treatment should be administered by the physician himself. This is particularly urgent in the first few weeks of the infection, when a day is worth more than a month in the later stages. The practitioner has no assurance that the injection that he has prescribed is going to soothe the inflamed urethra or irritate it. The only way for him to know what effect his treatment is producing is to watch the case from day to day and modify the treatment in accord with the reaction which it produces.

On the other hand, the physician has no right to assume that his patient can inject himself without causing trauma or increasing the existing inflammation in the urethra. A syringe and a bottle of medicine in the hands of an inexperienced layman may become a dangerous weapon when applied to a urethral mucosa already the seat of a virulent infection.

In this connection it is useful to remember that the urethral inflammation is not a stationary thing—it is an active, variable condition, changing from day to day and moment to moment. It is evident that the treatment must be adjusted continually, so as to harmonize with the pathological changes that are going on in the urethra; and it is these changes that must be watched carefully and properly interpreted by the physician if he would bring about a successful termination of the case.

The first two or three weeks determine the entire aspect of the inflammation. If it can be kept under control during these weeks it is safe to predict that the disease will run its usual course and a cure will result in a reasonable time. If, on the other hand, the disease is getting the upper hand, it is a safe prediction that complications and tedious chronicity are inevitable.

I find it convenient to divide the course of acute gonorrhea into three stages: The first is the stage

of increasing inflammation, which lasts about two weeks; the second is the stationary stage, which lasts about three weeks; this is the stage of maximum intensity and severity; the third is the declining stage, which lasts from two to four weeks. In this stage the acute symptoms gradually subside and the case proceeds to complete recovery. If the case can be so managed that the maximum intensity and severity of the disease are reached in the second or third week, the prognosis as to cure in a reasonable time is excellent. If the second or stationary stage is delayed unduly we may expect a long siege and a tedious one. The secret of success in the treatment of acute gonorrhea lies in one's ability to control the inflammation to the end that it shall be confined to the anterior urethra and reach its maximum severity in the second or third week. A cure is practically certain if the disease can be confined to the anterior urethra; whereas any extension to the posterior urethra, prostate, and seminal vesicles is a sure guarantee of complications and chronicity.

It is therefore of the utmost importance for the physician to see his patient every day, at least during the first stage, so that he may familiarize himself with the progress of the inflammation, and that he may see for himself whether his treatment is helping his patient or hurting him. When he gives the patient a prescription and tells him to come back in a week, it is impossible for him to watch the progress of the case, and in all human probability during those seven days considerable irreparable damage has been done. The posterior urethra has become involved and with it the prostate and the adnexa, and the process may go on until it stops only because it has no further tissues to attack.

During this period of watchfulness it goes without saying that the most important duty of the physician is to study the discharge microscopically and the urine passed by the patient macroscopically, at frequent intervals. The urine should be examined in two glasses at every visit—that is, every day; as soon as the second glass becomes turbid, posterior infection has supervened and the treatment must be adjusted to meet the new invasion. I do not feel that it is necessary to examine the discharge microscopically every day. Once the gonococci have been found we may be certain of their being present as long as there is a visible discharge with cloudy urine; it is only when the discharge becomes mucoid or watery and the urine becomes somewhat clearer in appearance that the microscopic determination of the presence or absence of gonococci assumes importance.

This importance is of two kinds. First, from the prognostic standpoint, it is essential to know whether the gonococci are gradually disappearing or holding on. In the latter event, the prognosis is bad in so far as the indications will point to a persistence of the infection in a more or less chronic form. Secondly, the importance of the microscopic examination is found in the therapeutic field. The general practitioner must accept as a good working rule the dictum that so long as gonococci are demonstrable, astringents must never be used in the urethra. It is therefore important to know at what moment the gonococci can no longer be demonstrated, for at that moment it is good practice to

begin the use of astringent injections. I know of nothing so successful in perpetuating a gonococcus infection in the urethra as an astringent injection employed while gonococci can be found in the secretions. This is one of the things the general practitioner should learn to avoid.

In those cases in which an astringent injection has not been used, but in which nevertheless gonococci are found notwithstanding the subsidence of the inflammation, we have a distinct indication that there is a focal point somewhere which has not responded properly to treatment. This focus must be determined and completely eradicated. It is in these circumstances that the most brilliant results are obtained by the employment of the urethroscope and dilatation.

In this connection it is well to emphasize a fact which is often disregarded, namely, that the absence of a urethral discharge is no proof that the disease has been cured. The practitioner must always bear in mind the fact that a urethral discharge is merely a symptom of the disease and not the disease itself. It is therefore perfectly possible for a patient to harbor gonococci while passing urine that looks normal to the naked eye. These gonococci may be hidden in the many urethral follicles, far removed from the reach of the injections, but they may nevertheless exercise their potential powers and set up a recurrence of the inflammation at frequent intervals.

The absence of pus from the urine merely indicates that we have passed from the acute to the subacute or chronic stage, and that we are dealing with the terminal or chronic condition. If in this stage treatment is suspended for a few days the practitioner will be surprised to observe a return of the discharge and the cloudiness of the urine, and he is quite apt to shift the burden of responsibility for the new outbreak upon the shoulders of the patient by accusing him of having reinfected himself at the shrine of Venus. The truth of the matter is, however, that there are a number of infected glands in the urethra which are harboring bacterial life, and as soon as repressive measures in the form of local injections are suspended these bacteria come into their own and make their presence evident by the recurrence of the discharge and the turbid urine. Endoscopy often reveals these glandular foci; it is no uncommon thing to isolate one or more of these foci and obtain a minute drop of its contents by squeezing, and when this drop is examined under the microscope myriads of gonococci and other bacteria can be demonstrated. In addition to these foci the urethroscope may reveal a hard or soft infiltration, constituting a stricture, in cases with a history of previous gonococcus infection. By its presence in the urethra this infiltration maintains a low grade inflammation which may often be kept under control by the use of local injections. As soon as these injections are stopped for any length of time, however, the gonococci which have remained latent resume their activity and a specific discharge is the result. It is therefore expedient as well as prudent for the practitioner to think of latent gonococcal foci in the urethra before accusing his patient of having exposed himself to a new infection. The patient may be telling the truth when he denies such exposure.

What has thus far been said refers to anterior

urethritis, that is infection involving the anterior portion of the urethra. When, however, the infection has traveled backward and has involved the posterior portion, the practitioner must be quick to recognize what has occurred. He must at once recognize the great risk of complications involving not only the genital tract, but the entire body as well.

His entire method of treatment must be modified to meet the new conditions, and here again he is thrown on his resources to the limit of his experience and capacity. If the prostate is involved he must recognize that fact and so adjust his therapy as to prevent the further extension of the inflammatory process to the seminal vesicles, vasa deferentia, and epididymides.

With the advent of prostatic involvement a new chain of symptoms is presented by the patient. Pain and frequency of urination are perhaps the earliest and most persistent of these symptoms; these are soon followed by vesical tenesmus more or less severe in character, caused by the inflammation at the neck of the bladder. Painful and frequent erections, commonly known as chordee, soon appear to make life miserable for the Neisserian victim; and as the process extends we are soon brought face to face with the most painful of all these complications—acute epididymitis. Usually, the inflammatory process ends here, and the disease settles down to a respectable chronicity which generally takes months and even years to eradicate. In a minority of cases, fortunately, the infection becomes general in character and soon involves one or more joints or other portions of the body far removed from the original seat of the infection.

Now, in all of this painful chain of events the practitioner must be alive to what is going on and to the possibilities. Judging from the cases that come under my observation this is not always the case. In innumerable instances I have seen cases of acute prostatitis approaching abscess formation, with the vesicles also seriously involved, in which the practitioner has been treating the anterior urethra with hand injections, utterly oblivious of the fact that the deep urethra and adnexa have been seriously compromised, yet wondering why the patient does not respond to the treatment. In many instances the involvement of the posterior urethra was first brought to the physician's notice by the swelling in the epididymis.

Experts differ considerably as to the most satisfactory treatment of posterior urethritis and its extensions, and it would be beyond the scope of this paper to undertake even a brief consideration of this subject. It is sufficient to emphasize the point that excessive treatment is just as injurious in this part of the genital tract as it is in the anterior urethra. Irrigations of a mild antiseptic solution enjoy well-merited popularity in this condition; they should be combined with hot rectal recurrent irrigations, prostatic massage most gently administered, and anodyne rectal suppositories. The internal administration of alkaline salts combined with hyoscyamus and one of the santal oil preparations is also useful in alleviating the tenesmus and the chordee. When in spite of this treatment the acute symptoms persist, and there are chills and a rise in temperature, the practitioner may be sure that a prostatic abscess has formed and requires evacuation.

As to the seminal vesicles it may be said that they rarely, if ever, are separable in the inflammatory process from the prostate. All three organs are usually matted together in one hot, tender mass, and it is generally impossible to distinguish where the prostate ends and the vesicles begin.

When, however, the inflammatory process has passed through the ejaculatory ducts and involved the vas deferens and later on the epididymis, the diagnosis is simple enough. A hot, swollen, exquisitely tender epididymis, high temperature, and general prostration mark the climax of the infection, and the physician may indulge in the satisfaction of knowing that there are no further organs that can be involved in the genital region. And, curiously enough, as if to compensate the patient for his pains and loss of earnings, this inflammation of the epididymis occasionally results in a speedy clearing up of the urine and a complete cure of the original infection. Whether it is the high temperature, which inhibits the growth and the life of the gonococci, or whether it is because the inflammation has spent itself in reaching its climax in the epididymis, we are unable to say; but it is an undoubted fact that a speedy and complete cure has not infrequently followed the swelling in the epididymis and thus enhanced the reputation of the attending physician for skill and erudition in the treatment of gonorrhea. It is well, however, not to place too much reliance on this method of cure; for the epididymitis cannot, as a rule, be depended on to cure the gonorrhea. In most cases it is simply another complication that must be handled to the best ability of the physician, and nothing more.

Observation of many cases of this complication has convinced me that there is a distinct relationship between the therapy employed and the incidence of epididymitis. The attempt to force the cut-off muscle in the desire to irrigate the posterior urethra and the bladder, is, in my opinion, the most prolific cause of acute epididymitis; the second most frequent cause is the employment of strong irrigating solutions, principally strong permanganate of potassium. To be sure there are cases which would probably develop epididymitis and every other conceivable complication under any form of treatment, or under no treatment whatever; but these are exceptional. The average case of gonorrhea responds kindly to gentle treatment and represents in no uncertain terms the application of harsh measures, principal among which is the forcing of the cut-off muscle in the Janet or Valentine technique.

The treatment of this distressing condition is no secret. Rest in bed need not be urged upon the patient; he cannot do otherwise. Elevation of the scrotum, so as to eliminate the drag on the inflamed inguinal cord, is most welcome. Local applications of heat or cold have enjoyed a long-lived popularity, but no one can say which of the two is more soothing in any given case. Both must be tried. It is well to remember that this treatment is merely palliative at best; we hope to reduce the inflammation to the point that the patient may be able to get out of bed and return to his work, but the swelling remains for a long period, mute evidence of the inefficiency of our treatment. Incision into the pus focus, with drainage, is far more ef-

fective, from the standpoint of relieving the acute inflammation as well as that of the future functional effectiveness of the organ. Unfortunately this treatment looks more radical than the ice bag or the hot poultice, but in the long run it is by far the more conservative and effective.

A word as to serum and vaccines in acute gonorrhea. So far as my experience goes I have been unable to see any benefit resulting from their employment in any acute complication of gonorrhea except arthritis. In this condition they are undoubtedly of great value, and should be used freely. In acute epididymitis, prostatitis, and vesiculitis they seem to have no value whatever.

Finally, the practitioner should know that arthritis following gonorrhea may be due to the gonococcus infection, or may not. All swellings of the joints are not necessarily gonorrheal in character, even though they occur during an attack of gonorrhea. On the other hand, it is equally important to remember that gonorrheal arthritis may recur with each new attack of acute urethritis, even though the urethral attack be a mild one. There may be no apparent connection between the one and the other; nevertheless the tendency to recur during subsequent urethral involvements is worth remembering. In these cases it will be found that vaccines are far more effective than the salicylates.

113 EAST NINETEENTH STREET.

MELANODERMA ARSENICALE PRODUCED BY CACODYLATE OF IRON.

BY DOUGLASS W. MONTGOMERY, M.D.,
SAN FRANCISCO, CAL.

MELANODERMA arsenicale, or arsenical pigmentation, is not caused by a deposit of the metal, as is argyria, but is due to an increase of the normal pigment of the skin. Brunettes are presumably, therefore, more inclined to this disfigurement than blondes, but I do not know that they really are so. It may occur when taking small doses of any form of arsenic, but it usually requires large doses continued through a considerable length of time for its development. It is slow in coming and as slow in disappearing, and causes no symptoms except the discoloration.

In giving arsenic internally for psoriasis or lichen planus, on the eruption clearing up, a pigmentation is occasionally left on its site. This, of course, is quite different from the instance under consideration, in which no such eruption was present.

An Irishman, over seventy years of age, whom I had treated a year previously with salvarsan and mercury for an old lues, was given the cacodylate of iron because of a profound anemia. He received nineteen doses of one grain each, given within twenty-five days, from May 11, to June 4, 1915, inclusive. At first his hemoglobin mounted quite rapidly, but came to a standstill while yet far below the normal. After taking the nineteenth dose, he said he was beginning to look very dirty, although he bathed frequently. On stripping he showed characteristic arsenical, dirty, reticulated pigmentation of the skin across the lower part of the abdomen, and on the temples and forehead. The mottling or reticulation was due to lighter areas, which

in some places were quite clear. The pigmentation slowly vanished on ceasing the administration of the drug. Subsequently, under the care of a friend, he was given a more rigorous course of this same drug, and developed both an alliaceous odor to his breath and characteristic cutaneous pigmentation, which again cleared up after stopping the use of the cacodylate.

There was no evident reason why the patient should be so susceptible to this particular arsenical reaction. He was anemic, he had always a trace of albumin and a few hyaline casts in his urine, and he suffered severely from sciatica. He was spare in build, active in habit, and had the pale skin usual with the northern European races, and in accordance with his age it was normally atrophic. Although the kidneys, as above shown, were not free from disease, yet they functionated well, and the cacodylate given either by me or subsequently produced no renal symptoms.

The above case also is interesting because a relatively non-toxic arsenical preparation, a cacodylate, had caused a marked and characteristic pigmentation of the skin in an unusually short time. The total quantity of the drug given, as before stated, was nineteen grains, or about 1.14 grams, divided into moderate doses of one grain, or 0.06 gram each, spread over a period of twenty-five days. That the pigmentation was due to the arsenic there was no doubt; it appeared during the administration of the drug; it disappeared on ceasing to administer it, and it reappeared on resuming this form of medication, to disappear again when the drug was discontinued.

When I first viewed the pigmentation I thought of the chloasma of anemia, because the patient was anemic, and also because chloasma occurs most frequently on the face, especially over the forehead and temples. This, however, did not account for the more marked pigmentation, definitely reticulated, over the lower part of the abdomen. Then I recurred to a possible cachectic pigmentation from tuberculosis or malignant disease of the abdomen or even Addison's disease. These possibilities were all the more immanent because the persistent and severe sciatica had led myself and others to a search for tumor pressure. Syphilis was another contingency, pertinent, because the man undoubtedly had, years before, acquired this disease.¹ The pigmentary syphilide, however, usually occurs in women, and about the neck, and is a consequence of a foregoing secondary eruption. Neither the sex, nor the situation, nor the time of this pigmentation, therefore, agreed in the present case with a possible syphilitic origin.

The Dosage of the Cacodylates.—That the above mentioned dose of 0.06 of cacodylate of iron is a moderate one may be seen by comparing it with the doses of cacodylate of sodium as formulated recently by Gougerot for subcutaneous injection.

Daily weak dose 0.06 to 0.08 gm.
Daily moderate dose 0.10 to 0.08 gm.
Bi-weekly strong dose 0.30 to 0.40 gm.
Weekly, exceptionally strong dose, 0.60 gm.²

Theoretically the formula for cacodylate of iron is $(\text{CH}_3)_2\text{AsO}_2$, Fe, and therefore contains three cacodyls to the cacodylate of sodium's one, but iron

is so much heavier than sodium that the amount of arsenic in each is about the same. According to the above formula the cacodylate of iron should contain 48.17% of the metal arsenic (As). How closely the cacodylate of iron found on the market corresponds to the theoretical formula is not known. Assuming, however, that the above is correct, this patient received nine and one-tenth grains of the metal arsenic (As) in twenty-five days.

Wm. A. Pusey has reported an instance in which a patient, seventy years of age, developed an intense pigmentation after taking, during one month, five hundred minims of Fowler's solution.⁴

This solution of potassium arsenite does not contain 1 per cent of potassium arsenite as generally assumed, but instead the amount of potassium arsenite equivalent to 1 gm. of arsenous acid (As_2O_3) in 100 cc. of the finished solution. On the basis of 1 gm. of As_2O_3 in 100 cc. of Fowler's solution, 100 cc. of Fowler's solution contains 0.757 gm. of the metal arsenic (As), and one minim of Fowler's solution contains 1/140 grain of the metal arsenic (As)³. Therefore five hundred minims, the quantity administered in Pusey's case, would contain 3 4/7 grains of the metal arsenic (As), an amount of the metal much less than in my case.

The two drugs, arsenite of potassium and the cacodylate of iron, cannot, however, be compared on the basis of their arsenic content alone. The metal in some of the organic combinations is not nearly so toxic as it is in the inorganic combinations, for instance, when bound with cacodyl, as in the cacodylates, or with the benzol rings, as in salvarsan. It is also now recognized that neither of these organic combinations is so active therapeutically in cutaneous diseases as the arsenite of potassium. The interest in the present case lies in the very active effect of the cacodylate of iron in producing a pigmentation of the skin.

Hyperpigmentation in Its Relation to Other By-Effects of Arsenic.—The by-effects of arsenic are: (1) A disagreeable granular feeling of the conjunctivæ, (2) Puffiness of the lower eyelids, (3) Congestion of the hands and feet, (4) Dryness of the throat, (5) Disturbances of the stomach, (6) Diarrhea, (7) Increase of the quantity of urine, (8) Urticarial eruptions, (9) Erythemas (for example the Jarisch-Herxheimer reaction), (10) Pigmentations of the skin, and (11) Hyperkeratosis, especially of the palms and soles.

Hyperpigmentation is not an infrequent consequence of the administration of arsenic when given in large doses and for considerable lengths of time. In my experience, however, it is not nearly so frequent as irritation of the conjunctivæ and puffiness of the lower lids. Borsellini says⁵ that it occurs nearly as often as congestion of the hands and feet, and much more frequently than keratoderma of the palms and soles. Its appearance varies in different cases in its topographical distribution, in the size of the patches, and also in its intensity. There may be only a few disseminated yellowish brown patches, or there may be all the grades between this and a generalized continuous melanoderma simulating Addison's disease, and only distinguishable from it by the lack of pigmentation of the mucous membranes.

All the above by-effects are exhibitions of the

physiological actions of the drug. Arsenic undoubtedly stimulates the epithelial covering of the oculo-respiratory, gastrointestinal, genitourinary and cutaneous systems, and the stimulation of such vast epithelial sheets, which are essentially gland fields spread out instead of being folded into tubes or bunched into lobuli, as in the acinous or lobulated glands, would account at least in part for the well known tonic effects of the drug.

This stimulation, however, does not occur equally in all cases neither as distributed throughout the vast areas above enumerated, nor in individual situations. For instance, I have observed repeatedly such a small dose as one-fiftieth of a grain of arsenite of potash or of arsenous acid given three times a day to cause most annoying irritation of the neck of the bladder. In the present instance reported, there was marked stimulation as far as could be ascertained, of only one function, the pigment forming function of the skin.

NORMAL AND ABNORMAL PSYCHIATRY.

By B. LEMCHEN, M.D.,

DUNNING, ILL.

PHYSICIAN TO THE CHICAGO STATE HOSPITAL.

NORMAL psychiatry or the normal mind is easily understood as the activity of the nerve cells. We know that nerve cells conduct, transmit, retain, and originate stimuli. The neurons are in close connection with the other cells of the body and almost constantly receive information from the whole body through the sense organs, also from outside the body; a good deal of this information is retained as symbols at the associated centers. For comparison, we may divide it into three parts: (1) sense organ where stimuli are received; (2) sense center where the stimuli from sense organ are brought to be registered and transmitted to; (3) associated centers, where the stimuli are again registered and compared with symbols of previous stimuli from the same and other sense organs and elaborated into an object.

For instance, waves of light will emanate from an object and will reach the cornea where they are refracted and an inverted image of the object will be formed on the sense organ of sight, the retina. From there the stimuli will be carried to the center of sight which is located in the occipital lobe where they will register and be carried to the associated centers where they will again be registered and compared with symbols of former stimuli from the same sense organ and also from other sense organs. Not only do we recognize the object as a different object but also the name of the object. If the object was a house we also know the name

house because we were once told the name of house, and the center of hearing has also registered it at the associated centers; and if the same has told us the house belongs to John Smith we will also recognize it because all centers of sense organs converge and symbolize in the associated centers and, besides, the special centers, the associated centers also receive information regarding the frame work, muscles, and viscera, which are known as muscle sense, bone sense, visceral sense, sense of position, pain, touch, heat, etc.; and the associated center will receive from the sensory nerves, in the cornea, the sizes and shape of the light waves; from the nerves of the eye muscles the amount of convergence necessary to see the house single; from the retinae, the sizes of the angle, the kind of color, etc., so the associated centers not only will recognize that it is John Smith's house but also the size and color of the house and the distance from the house to the person seeing it.

All this is due to the activity of the nerve cells or neurons. Physiologists have worked out well the mechanism of the neurons and we know now that a stimulus from the periphery has to transverse a number of neurons until it reaches the associated centers and pass again from the associated centers to the periphery.

The neuron has a cell body with numerous processes. At one end the processes are known as dendrites and at the other end as axons; in the bipolar cells one axon, in the multipolar cells several axons are present. The stimuli are received at the dendrites, transmitted to the body, and from the body to the axon. An axon of one neuron ends in close contact with a dendrite of another neuron but they are not continuous and the space between is known as synapsis. The dendrites have branches and so have the axons; the latter are known as collaterals.

Had psychiatrists, in the study of abnormal psychiatry, also studied the unit of the neurons or the cells, the difficulty, perhaps, would not have been so great; instead their studies have been more or less confined to psychoses; and while the classification of the different forms of psychoses were of value in prognosis (for instance, we know that a dementia precox psychosis has a poor prognosis and manic depressive is of good prognosis) still the causes of insanity, at least the functional ones, have not as yet been explained, while in the study of neurons we can find some explanations to the symptoms of insanity.

Why do stimuli travel from the dendrites to the bodies and from the bodies to the axons and to other neurons in a more or less uniform rate? There are no batteries and neither is there a closed circuit; in fact, the neurons are not continuous but there is always some space between them. Our answer must be that it is due to the intelligence or experience of the neurons themselves.

In the stages of evolution the neurons have specialized themselves in transmission of stimuli in a second direction and unit of time, also to recall, compare, and originate stimuli; and it is needless to say that in organic brain diseases, where there is an actual destruction of neurons, we may have any or all of these functions lost in a second part of the nervous system, and we may find that a normal person after a cerebral insult will show symptoms from a slight amnesia to profound idiocy.

But even where there is non-destruction of neurons, we can readily understand what may happen under abnormal conditions. First, the nervous system is not a closed circuit but there is always a small space between the axon of one neuron and the dendrite of another neuron, or the synapsis, and there are no batteries driving the stimuli from the dendrite to the body and from the body to the axon and to the next neuron, this being due to the effort and intelligence of the neurons that stimuli are so transmitted and the neurons may become fatigued from over-stimulation and not be able to transmit stimuli. In fact, it does happen when a person reads for a long time, that there comes a time when he cannot temporarily see the print or, when he writes a long time, he may, for a while, not be able to write. It is known that managers of corporations, when they write many checks, finally reach a point where they cannot sign their own name. Also, a person may become temporarily deaf from too much noise after an explosion, etc. Also abnormal substances circulating in the body or inherited tendencies of the neurons may retard or accelerate the transmission of stimuli, and we may have retardation of thought and movements with its accompanying depression, or flight of ideas with euphoria, or combined retardation of thought and acceleration of movements with its accompanying anxiety and restlessness. The cells may become poisoned and instead of transmitting the stimuli from the dendrites to the body and from the body to the axon, may allow the stimuli to travel either way and instead of a stimulus traveling from a center reaching the associated centers, making an impression and recalling symbols it may travel back and forth from the center to the associated centers and back to the center, and arouse old memory pictures or what we commonly call illusions, while the stimulus itself is not remembered. Also in the case of intoxication from infections or drugs, like alcohol, a person sees and hears imaginary objects with a partial or complete amnesia according to the number of stimuli retained during the period of intoxication. The neurons may be so poisoned that they are unable to transmit some or all stimuli, and the person will be partially or wholly unconscious. Under great over-stimulation the axon of a neuron may be deflected from its course and transmit its stimuli to a neighboring neuron instead of to the previous neuron and the stimuli may then reach the associated centers through a new channel and as such daze the person. We know that in the circulation, cases of engorgement of the vessels may twist themselves, and why cannot the same thing happen with the neurons? Of course, the blood vessels are continuous and the blood can flow in only one direction, but the neurons are not continuous and this is probably what happens after earthquakes, shell shots, etc., where, after recovering consciousness, the person still remains dazed and hallucinates with accompanying delusions for some time afterwards, although the special centers receive the stimuli as formerly, but through different channels.

The neurons through inherited or acquired weakness may misdirect or block stimuli, and this is probably what happens in that form of psychoses known as dementia precox. A stimulus originating in one organ may be misdirected to a center of another organ; for instance, a stimulus that origi-

nates in the stomach or skin may be misdirected and reach the center of hearing and the person will claim that someone in his stomach or leg talks to him; also a stimulus may be blocked and the person will be unable to do what he intended to do, or the stimulus may be misdirected from its origin in the periphery, and the person will do just the opposite of what was asked of him—negativism. Or the stimuli may be so completely blocked that the person may be unable to move even under danger, although the special centers receive stimuli, and the person sees, hears, etc.—catatonic stupor.

It is hardly necessary for me to mention that people with misdirected stimuli will misinterpret ordinary happenings and develop delusions. What are we to do for the insane? In those cases which are due to organic brain disease, we must prevent the organic brain disease. The majority are due to syphilis and to arteriosclerosis, and in their prevention the general practitioner is more capable than the psychiatrist, as he comes in contact with more homes. This is also true in intoxication psychoses. Those due to inherited or acquired weakness of the neurons I must leave to the obstetrician and pediatricist to advise the pregnant woman how to take care of herself during pregnancy and to advise parents how to raise their children, and to the social workers for them to help the poorer classes so they can carry out the physician's advice. All I can do is to say how to care for the actual insane. First of all is an early diagnosis because, when the proper treatment is instituted early by eliminating all sources of excessive irritation and especially of gastrointestinal origin with proper training, a good many of them may be cured; it must always be remembered that automatism or habit plays a great rôle in an individual's life. This is primarily due to nature's desire to economize, as it can be readily seen if we had to apply consciousness to every act in our daily life and symbolize every act, then the number of neurons or size of our brains would have been all out of proportion to our bodies; but by repeating things the neurons are capable of performing again the same thing without registering them into consciousness; this is not only a saving of extra neurons, but those existing are capable of doing it even better, by comparison with previous symbols.

In the treatment of the chronic insane, besides general treatment for bodily defects that may be present, the only methods that have proven of value are hydrotherapy and reeducation by finding the proper occupation for the individual patient.

For the following reason it is absolutely necessary for our hospitals for the insane to have a sufficiently trained medical staff to direct the proper occupation for the patients. Occupation for the insane is really a medical problem, and in accordance with the old saying, "in time of peace prepare for war," now is the time for hospitals for the insane to train men in this line of work, as insanity is bound to increase and we should have men capable of meeting it.

Nature of Rabies Virus.—Remlinger believes this to be a transition between a vegetable organism and an inorganic substance, the latter a colloid with diastasic properties.—*Le Progrès Médical*.

SOME MEDICAL ANTECEDENTS.

By J. A. HAGEMANN, M.D.,

PITTSBURGH, PA.

OTORHINO-LARYNGOLOGIST TO THE PITTSBURGH HOSPITAL.

WHEN Solomon gave expression to his famous aphorism "there is no new thing under the sun" (Ecc. 1-9) he was possibly a bit blasé. It is conceivable that one so numerous polygamous might have run the gamut of human emotions, and that multifarious experience had made him sage. Perhaps he intended to convey the truism that matter does not come into existence *de novo*, each encountered form being but a transmutation of preceding syntheses. However that may be, it is an interesting circumstance that unequivocal innovations in the realm of medicine are rare. In corroboration of this statement some examples will be cited. The fundamental principles underlying our present conception of antitoxin production was probably elementarily and speculatively known to Arnold de Villeneuve, one of the Alchemists, who lived from A.D. 1245 to about A.D. 1311. According to "Mackay's Extraordinary Popular Delusions" (page 104), M. Harcouet attributed the following recipe for the prolongation of human life over several centuries to Villeneuve: "If he be of a sanguine temperament, he shall take sixteen chickens, if phlegmatic, twenty-five, and if melancholy, thirty, which he shall put into a yard where the air and the water are pure. Upon these he is to feed, eating one a day; but previously the chickens are to be fattened by a peculiar method, which will impregnate their flesh with the qualities that are to produce longevity in the eater. Being deprived of all other nourishment till they are almost dying of hunger, they are to be fed upon broth made of serpents and vinegar, which is to be thickened with wheat and bran. . . . They . . . are to be washed down with moderate quantities of good white wine or claret. This regimen is to be followed regularly every seven years, and anyone may live to be as old as Methuselah."

About 1675 Helvetius came from Holland to Paris to practise medicine. A drug merchant whom he had attended gave him as a fee a packet of *Ipecacuanha* root, imported from Brazil. Helvetius empirically discovered that the root had the virtue of healing dysentery. By curing that disease he accumulated no less than 100,000 crowns, and, in addition, became a favorite at the court of Louis XIV. In the journals of today one notes frequent reference to the use of emetine for counteracting the baneful effects of endamebae. That sounds different, but the interactions are identical, whereas modern compensations are much less princely.

Robert Hunt in his volume, "The Poetry of Science" (London, 1854), page 408, quotes Prof. Graham to the effect that "the permeation of any radiant body through fixed solid matter is entirely a question of conditions." Yet nothing was known of the x-rays until 1895.

In 1861 Paul Broca published the memoir wherein he propounded that aphasia is associated with injury to and consequent inaction of the posterior portion of the third frontal convolution

on the left side of the brain. This area is now universally known as Broca's space. Sir Francis Galton fruitlessly searched the archives of medicine for a single reference previous to Broca's publication of the circumstance that paralysis of the right side of the body is usually accompanied by loss of speech. Yet Dickens, in 1848, in *Domby and Son*, Chap. XXXVII, had capably described the last illness of Mrs. Skewton from just that affliction. His delineation of her speechless state, her staring at the ceiling, the making of inarticulate guttural sounds in answer to questions, well depict the symptom—complex of hemiplegia. The gradual recovery of some motion in the right hand, though not of speech, shows fidelity to nature in a remarkable degree, particularly admirable when emanating from the pen of a non-medical author.

In the former villa of Pope Julius III, in Rome, which is now used as an Etruscan museum, there is exhibited an excellent specimen of a gold dental bridge in proper position in a skull taken from an Etruscan tomb in *Civita Castellana*, a town in Etruria, situated upon the presumed site of Veji. The latter town was utterly destroyed before the time of Christ; so a conservative estimate would put the age of this dental bridge at over 2000 years.

John Timbs, F.S.A., in his book "Doctors and Patients" (London, 1876), page 341, cites the case of a Mr. Brunel, who, while juggling a coin to amuse his children, had the misfortune to have the half-crown drop into his windpipe. Mr. Brunel, being an engineer, had an apparatus constructed in the shape of a platform hinged in the center so that it could be tilted up or down. He had himself strapped upon this, and by inverting his body by means of the movable platform succeeded in displacing, though not expelling, the coin. This caused such violent coughing that further attempt at that time was postponed. Two days later, April 25, 1843, the operation of tracheotomy was performed by Sir Benjamin Brodie, he intending to extract the coin with a forceps, if possible. In this he was unsuccessful. The incision in the windpipe was kept open by inserting a quill or tube until May 13. Then his body was again inverted, his back struck gently, and the coin was expelled after having been in the right bronchus for six weeks. And all this took place seventy-five years ago! Verily, novelties are as rare as blue diamonds!

Hysterical obmutescence occurring in children and persisting with exasperating pertinacity is occasionally encountered. Herodotus, who was born about 484 B.C., narrates that "Cræsus had a son . . . who was in other respects proper enough, but dumb. . . . When the city was taken, one of the Persians, not knowing Cræsus, was about to kill him. Cræsus, though he saw him approach, from his present misfortune, took no heed of him, nor did he care about dying by the blow; but this speechless son of his, when he saw the Persian advancing against him, through dread and anguish burst into speech and said, "Man, kill not Cræsus!" These were the first words he ever uttered; but from that time he continued to speak during the remainder of his life." (From Henry Cary's translation, 1898, page 27.)

In Jeremiah 31-29, we read that "the fathers have eaten a sour grape, and the children's teeth are set on edge." During the past century Dr. Hutchinson made similar statements, but we will not charge him with plagiarism.

Further examples of medical foreshadowings might be adduced, but a sufficient number have been mustered to substantiate the sentiment so tritely expressed by Mademoiselle Bertin (milliner to Marie Antoinette), "There is nothing new except what is forgotten."

HIGHLAND BUILDING.

A NEW METHOD OF MORE ACCURATELY DETERMINING THE UPPER BORDER OF THE LIVER BY MEANS OF PERCUSSION.*

BY GEORGE L. LAPORTE, M.D.

NEW YORK.

ASSISTANT PROFESSOR OF CLINICAL MEDICINE, COLLEGE OF PHYSICIANS AND SURGEONS.

WHILE investigating the accuracy of percussing the outlines of the heart as controlled by fluoroscopic examination, it was of course necessary to determine the upper border of the liver. In the first series of cases, in which this was done by the old method of percussing from above downward until liver dulness was reached, the results were very unsatisfactory. In fact it was found to be more difficult to percuss correctly the upper border of the liver than the heart dulness.

I finally devised the following method, which has given more accurate results.

I percuss from above downward in the mammillary line, laying the end phalanx of my index finger firmly on the chest wall parallel to the ribs and using a medium strong percussion stroke. At the first change of sound from clear pulmonary resonance to a somewhat duller sound a line is drawn on the chest wall. Then I place my finger over the liver dulness at the lower costal margin and percuss with the lightest possible percussion (threshold percussion, so light that over liver dulness hardly any sound is audible) upward until a slightly more resonant percussion sound is perceived (lower lung border). Another line is placed on the thorax at this point. The true upper liver border lies half way between these two lines.

In all I percussed 100 cases to determine the upper liver border, all of which were controlled fluoroscopically by Dr. Thomas Scholz, Roentgenologist to the Montefiore Hospital. The x-ray tube was placed at a distance of 1.5 meters from the patient and the border of liver marked by pliable wire fastened by adhesive plaster. Of these 100 patients 41 were examined by the old method. In the vast majority of these, the upper liver border was placed too high, sometimes as much as 5 or 6 cm. Fifty-nine cases were percussed by the new method and the results were found to be much more accurate, very frequently exact, and seldom varying more than 1 cm.

I claim for this method that it is not only more accurate, but that it is also much easier to learn

*From the Medical Wards of Montefiore Home and Hospital, New York City, N. Y.

than the old way. In teaching third year medical students I have had much less trouble in having them acquire proficiency in outlining the upper border of the liver than in percussing the borders of the heart.

The important point to remember is that in percussing from above downward one must use a medium strong percussion stroke, and note the very first change of percussion sound, and similarly when percussing from below upward employ only the very lightest, scarcely audible percussion.

129 EAST NINETY-FIRST STREET.

Medicolegal Notes.

Charitable Hospitals Liability to Physician for Negligence of its Servants.—Action was brought by a physician against a charitable hospital for personal injuries received under the following circumstances: The defendant conducts a hospital where medicine and surgery are practised. In one of the rooms there was an x-ray machine into which room the plaintiff, a practising physician, went with a patient, a little girl, to get a radiograph of the child's head. The child's father sat on a chair in front of the x-ray machine with his daughter on his lap. The plaintiff attempted to comply with a request of the operator of the machine to hold the child's head, the plaintiff's own head at the time being near the wires which carry the electric current to the x-ray tubes. After the electricity had been applied to the wires the plaintiff fell to the floor, breaking his left leg. The defendant was charged with negligence in placing the plaintiff where his body made a short-circuit for escaping electric currents; in failing to warn the plaintiff of the dangers of such close proximity to the wires; in failing to use an available appliance to keep the wires a safe distance from the plaintiff; in failing to place the x-ray machine where the dangerous wires would be vertical, thus keeping them at a safe distance; in failing to provide a competent and experienced x-ray operator. One of the defenses was that the hospital was an eleemosynary institution and that as such it was not pecuniarily liable for the negligence of its servants. This proposition was based on the following principle of law: "A charitable institution conducting a hospital solely for philanthropic and benevolent purposes is not liable to inmates for the negligence of nurses." *Duncan vs. Nebraska Sanitarium & Benevolent Assn.*, 92 Neb. 162, 137 N.W. 1125.

As to this the court said: "In the case cited immunity from liability is limited to 'inmates.' The rule thus announced has the support of precedent, but in a recent opinion of the Supreme Court of Virginia, after an extended analysis of the cases, it was held that the doctrine of nonliability to inmates did not extend to strangers, the modern theory being as follows: 'One who at the request of a patient about to enter a hospital accompanies him to render reasonably necessary assistance is an invitee of the hospital, to whom it owes the duty of exercising ordinary care to have the premises reasonably safe.' *Hospital of St. Vincent de Paul vs. Thompson*, 116 Va., 101, 81 S.E. 13, 51 L. R. A. (N.S.) 1025. In a recent article on hospitals it was said: 'The theories of the immunity of a hospital from liability on the ground of public policy and on the ground that the assets are a trust fund having been very generally rejected by the courts, and the doctrine of waiver by acceptance of benefits being applicable only to patients, the law has come to be that as to others not the recipient of the institution's charity the rule of responsibility for the negligence of its servants and agents is applied as in cases of the ordinary business corporation.' 13 R. C. L. 948, sec. 12. This view of the law conforms to correct standards of justice, and defeats the immunity pleaded in the answer of defendant." Judgment for the plaintiff was affirmed.—*Marble vs. Nicholas Lenn Hospital Assn. of Omaha*, Nebraska Supreme Court, 167 N.W. 208.

Military Medicine.

REHABILITATION OF THE DISABLED SOLDIER.

At the sixty-ninth annual meeting of the American Medical Association, held in Chicago, June 10-14, 1918, Thursday, June 13, was devoted to addresses and papers dealing with the rehabilitation of the disabled soldier.

Lt.-Col. FRANK BILLINGS of Chicago opened the session with a few words, saying that the huge audience, filling the Auditorium Theater, had met with the one aim, to combat the monstrosity on the other side and to give those men, who had given their all, the means of being restored to full economic and civil life.

SURGEON-GENERAL WILLIAM G. GORGAS, U. S. A., in his opening address said that the question of reconstruction was a new one to the U. S. Army, as it was to military life in general. It was a product of the present crisis. Formerly the whole aim of war was to defeat the enemy, and the wounded were neglected, being merely a drag on the fighting men. Doubtless, if necessary, the army to-day would do what its ancestors did—sacrifice the wounded, if this should become necessary for the defeat of the enemy. Savage tribes killed off the wounded who were unfit to march, but nowadays the great function of surgery is to put men back in the fighting line, if fit; and if not, to restore them to their own country with the least possible delay. Statistics of the Canadian Army gave a very good idea of what would have to be done in this country in the way of conservation of the wounded. In four years Canada had contributed 350,000 fighting men, and of these 10 per cent. had been returned for reconstruction work. The United States could expect about the same proportion of wounded men to be returned. This was the modern viewpoint of the duties of the military office, and the country undertook, as a debt that it owed to these men, to restore them to full civil efficiency and to the capacity to enjoy life in their own homes.

The National Program for the Reconstruction and Rehabilitation of the Disabled Soldiers.—Dr. FRANK BILLINGS of Chicago said that the complete program included the care of the soldier from the time that he fell in battle to the time he was restored to full civil and economic usefulness. Congress had recently passed a law which placed the wounded man under the jurisdiction of the Federal Board for Functional Reeducation. The maimed man was put as soon as possible in touch with reeducational work, the general hospitals being in part reconstructive and embracing facilities for prevocational training. Thus men very early in their disability were being established in new and gainful occupations. Hotels and institutions were established as hospitals in the sixteen military districts of the country and the enlisted man was sent to the center nearest his home. It was hoped in time that these general and reconstructive hospitals would become State institutions. The scope of the plan was very comprehensive. The hospitals included, besides the medical and surgical departments, wards, gymnasiums, laboratories, hydrotherapeutic and electrothermic departments, grounds for drill, exercise, and games. The British government had lent the services of Sir James McKenzie to standardize physiotherapeutic measures. Mr. James F. Russell, Dean of Teachers' College, New York, had been chosen to enroll all the technical and physical educators necessary.

Reconstruction and Rehabilitation Problems as Demonstrated by Experience in Foreign Countries.—Col. CASEY A. WOOD of Chicago said that Canada, with her democratic ideals and her sense of duty toward the disabled soldier, was the country to which the United States must look for help in the reconstruction problem. Canadians had early discovered that the hospitalized soldier developed a peculiar psychic state which was fatal to rehabilitation. Social service workers were then called upon to institute the "cheer-up program." They visited the wounded and kindly, but firmly, insisted on the doctrine of social reconstruction. The employment of films was found to be of the greatest service in showing the disabled what resources were still left to them. They were inspired by having thus graphically shown them what others had accomplished. Furloughs for the disabled were discounted, as a continuous uninterrupted effort was neces-

sary until the men were reinstated in civil life. Idleness and inertia were the greatest foes of the disabled soldier. A judicious mixture of work and play was the best medicine. The educational program aimed to reach three classes of citizens—medical officers and teachers, soldiers, and the public. The more the man's own family understood the scope of the plan the easier was the task of the government, therefore propaganda and publicity were essential to prepare the public mind. To this end the little magazine, *Carry On*, was being published and distributed from the Surgeon General's office. In this the experience of other nations was translated into the particular needs of American soldiers.

The Surgeon General's Plans for Receiving, Transporting, and Distributing of the Disabled from Overseas.—Col. R. E. NOBLE of Washington, D. C., read this paper. The wounded were tagged and graded according to their disability, from the time they left the fighting line. If not fitted to be returned to the front within six months, they were brought back to this country. A specially selected officer was detailed to receive the hospital ship at port, and to choose which hospital was to receive the cases. This officer was specially trained in transportation problems, and he indicated the type of coach and the number of coaches in which the men were to travel. Detachable unit cars, with a staff of doctors and nurses, were included in each train, and these could be sent to any part of the country with small numbers of wounded if necessary, instead of having to deal with trainloads of men. The trains themselves included every comfort for the sick; dining cars, kitchen cars, cars for the staff, and sleeping cars. The cars were to be unloaded actually at the doors of the hospitals, which were scattered about the United States according to the military districts. These hospitals were of the pavilion type; in one sense they were general, in one sense reconstructive.

Acute Surgery as Related to Reconstruction.—Col. G. SEELIG, M.C., U. S. A., presented this communication. The word reconstruction had physical, psychic, and functional significance. Acute surgery was part of its scope. The latter not only covered war traumata, but also acute surgical diseases occurring in camp. It began at home, although many new surgical principles had been evolved in actual warfare. It had, however, to meet greater demands than did civil surgery. Most men had spent nights in Gethsemane over the failure of well-meant surgical procedures. They had consoled themselves by the thought that they had done the best that could be done. Now, however, the army surgeon was engaged to return the man to civil life in such shape that he had no grounds for a claim as a pensioner. The soldier had to submit to operation to make him fit to fight, and when he was no longer fit the government had to give him surgery to make him as fit for civil life as possible. Much surgery would be done on home territory, but in the advanced zone the problem was seriously difficult and gravely depressing. The surgeon's judgment was harassed by the exigencies of transport, the rush of battle, the improvisations of warfare. Yet the fact of the man's future usefulness must not be lost sight of. The penalties of unnecessary operation were not mitigated by stress of battle. Neuroses, psychoses, asthenias were a direct result of front-line surgery for cranial lesions. Wrong surgical judgment at a critical time might produce spinal disturbances, bladder injuries, paralysis. Fistulae and collapse followed wounds of the lung; ischemia, the improper application of ligatures; extensive later operation would follow imperfect joint surgery. One could not, however, say where surgery ended and where reconstruction began. There was reciprocal relationship between the two branches. Both worked toward the one end—the future physical and economic well-being of the functionally compromised soldier.

Sir ARBUTHNOT LANE, referring to reconstruction work, said that the Red Cross Hospital in Kent was devoted especially to those extremely pathetic cases, patients with faces shattered or burned. These men were hideously disfigured and were removed from the sight of other patients until some reconstruction work could be done. To return them home, to the horror of their children, and perhaps fear from their wives, would be intolerable. Many surgeons were devoting their entire time to the reconstruction of these cases.

Dental surgeons first did plastic work, and later other specialists did reconstructive surgery. Twelve American surgeons were working there now, to their own great delight, and that of their British colleagues. Their experience would prove invaluable in the conditions arising in future in this country.

Lt.-Col. DAVID SILVER quoted Sir Robert Jones, who had said "the pathetic side of reconstruction was that of physical disabilities that ought never to have happened." This was not a criticism. Men were working under superhuman difficulties. The orthopedic surgeon had his special field in preventing later reconstruction work. In proportion as surgeons could employ primary suture of wounds did the cases of infection and adhesions diminish. Malunion and nonunion of fractures resulted from too frequent inspection and changes of methods of treatment. A committee on standardization of splints had therefore taken charge of this matter, to ensure uniform methods of treatment. Every man was to be trained in the fundamental mechanical principles of the brace. The levels of amputation, from the viewpoint of the artificial limb, were also standardized. Early application of the appliance was urged, as it had a distinct place in the mental rehabilitation of the patient.

War Neuroses.—Major W. HUTCHINS of Washington, D. C., presented this communication. The psychoneuroses of war differed from those of civil life only in that they were colored by incidents of battle. A heavy strain upon the nervous system was caused by the soldiers' life—the monotony, the constant exposure to danger, the sights of battle. Men who were mentally unstable were eliminated as far as possible, but those that did break down in the front line were treated in a different hospital from other patients. Their treatment was by actually stimulating work and wholesome recreation. They were always impressed with the fact that their case was hopeful and curable. Often they were able to gain increased efficiency and larger remuneration through the vocational training schools.

Sir JAMES MCKENZIE of London said that often when the soldier was nothing but rather "rattled" his disease was called "neurocirculatory asthenia." Medical men saw these patients often when they were merely overworked and needed a holiday. A simple interest in life and outdoor sports was the best cure. Games should play a large part in the reconstruction curriculum. The speaker had found that a little bit of a bet was sometimes a wonderful stimulus. Sport took these people out of themselves which was what they most needed. The question of heart murmurs in assessing the disability of the soldier would be a very difficult one. The common sense point of view was to consider, not the murmur, but the efficiency of the heart in its response to effort. Twenty years of watching these cases come and go, and grow up and grow old, had taught nothing but this rule. The younger men would do well to watch these cases for fifteen or twenty years, and at the end of that time they might be able to form a faint idea of what prognosis meant.

Re-education of the Deaf and the Speech Defective.—Major C. W. RICHARDSON of Washington, D. C., said that Hospital No. 11, Cape May, N. J., was selected as the Otolaryngological Center. The matron was to be one who had been head of one of the largest institutions for the training of the deaf. Sixty trained teachers for lip-reading had been selected. It was estimated that this work would require 1000 teachers per million cases of defects of hearing, and 500 teachers per million of defects of speech. War deafness was usually caused by shock concussion, affecting the labyrinthine structures, by detonation of high explosives. Progressive improvement occurred, and, after a time, recovery. Other cases, however, were caused by trauma to the auditory apparatus. Aphonias and voice changes were often due to nerve and muscle lesions with large loss of tissue. These cases were pitiful. They were looked upon with horror by the layman. No cases needed more aid than those with speech defects and facial mutilation, and great effort was needed to lift them out of the handicap class.

Reeducation of the War Blinded.—Col. JAMES BORDLEY of Baltimore spoke of this phase of the subject. One of the mistakes of the past, in not realizing the economic value of the blind, would now have to be recti-

fied. In this crisis, where every fraction of the brain and brawn of the nation was to be needed, the blind man must be placed where his economic value would tell. Professional and agricultural courses were to be opened to him. The hospital for the war blinded at Baltimore was so arranged that the blind man could be fitted to take a place in industry where he would be at no disadvantage. Not only he himself, but one member of his family, would be housed and educated free of charge, by the government, thus insuring that the families of the blind should learn the necessary attitude toward these people. Thus one of the most serious handicaps of the blind, the misplaced sympathy of the public, would be removed.

The Reconstruction of Canadian Crippled Soldiers and the Results.—Major J. L. TODD, Medical Officer of the Pension Commissioners of Canada, delivered this address, which he illustrated with a motion picture demonstration of the reconstruction work being done in Canada. In emphasizing the importance of reconstruction work he said that the success of this war was going to depend on what each one of us did here no less than on what our soldiers did over seas. If we were going to do what was right by our soldiers we must do it in the right way. It was natural for men and women to believe what the doctor told them and therefore the doctor should go about telling and teaching what reconstruction work for our soldiers meant. If they did this it would not be long until the doctor's opinion became the opinion of the general public. They had been taught that to waste at home was treason abroad and the object of construction was the conservation of our men. Actual knowledge was necessary on this subject if we were going to care for our soldiers properly. We all felt sentimental toward the disabled soldier or sailor just as we did toward an injured child, but to sympathize too much with either might be a bad thing. We might find it easier to coddle and pamper our disabled soldiers, but that was not the best thing for them; the best thing we could do for them was to put them back into some useful occupation. As an example of this, Sir William Osler recently went through a Canadian Hospital and found in one ward twenty men who had been gassed. After examining these men he said this was the worst case of hospitalization he had ever seen, for fifteen of the men were suffering from subjective symptoms alone, and, of the remaining five, three would be better off on their home farms than in the hospital. When the soldiers were in the Army they had everything done for them and, everything ordered, there was nothing left to their own initiative and it was bad for the men and bad for the country to allow them to continue in this way after their discharge from the Army. The country needed the fractional help that these disabled men could give, and the men must be made to feel this. The soldiers and the public must be made to feel that a pension was not a gift to make up for their lost capacity due to disablement. There was no doubt that after the Civil War in the United States the pensions were too small and later they had to be tinkered with, and the time came when these pensions were far greater than was justifiable. There should be but one authority in charge of the pension legislation and nothing should interfere with his responsibility. In Canada there was a committee that had charge of the pensions and there was no way of carrying things over the heads of that committee, and no one could get a pension unless it was rightly deserved. Major Todd showed pictures of the work being done at Hart House at the University of Toronto, where the men learned to use artificial limbs and other prosthetic appliances. The pictures showed how the limbs were made and repaired and the school room where re-educational work in certain lines was being carried on. In Canada the Government not only purchased the artificial limbs for the disabled men but kept them in repair, or, if worn out, replaced them. Their institution was of the type which the French called a reconstruction center, and there they also trained some who would go out and start other reconstruction centers as they were required. Through this work they would all come to regard the cripple very differently from what they had done in former years. They used to say: "There is a cripple, disabled in protecting our country; I owe

him much and I am supporting him." We would now say, "There is a cripple, disabled in the service of his country. I owe him much and he is able to support himself."

The Conservation and Reclamation of the Industrial Soldier; a War Measure.—Lieutenant Colonel HARRY E. MOCK delivered this address, in which he said, in part, that they had heard much the previous evening about brotherhood and brotherly love, and brotherhood was one of the things we were going to get out of the war. They had heard about the wonderful reconstruction work that was being done for the soldier and the sailor, and he wanted to speak of the work that should be done for the industrial soldiers who formed our second line of defense: these were just as necessary for the winning of the war as the military soldiers. When the industrial soldier was crippled he did not have the glory that came to the military soldier wounded on the battlefield, and he was not so well cared for. As to the relation of industry to the war, it had been said that in the beginning the war was a territorial war and then later it was a war of democracy, and now gradually, during this last year or two, it was becoming a war of social democracy. In Europe everything was being done to build up the industrial army to hasten the prosecution of the war. They had introduced everything for the protection of the industrial worker; they had built him comfortable and even beautiful homes, and they had given him shorter hours, and in many ways protected his health, because it had been found that when the industrial worker was living in a good environment and with shorter hours of work he did more work. This had led the workers to ask why if this policy was good in times of war it would not be a good one in times of peace. They would never go back to the old way after the war. The same would be true of this country, and, as this country was the first to stand for freedom, it must be the leader in this new democracy. The one thing we must think of first and foremost in connection with every question was whether it would help win the war. The industrial cripple was as much in need of reconstruction as the disabled soldier and sailor, and we must find some means of reclaiming the injured members of the industrial army. The speaker exhibited statistics showing that in the industrial army of 30,000,000 in the United States there was annually a far greater number of men needing reconstruction than there would be in the military army. A plan for such reconstruction work had been worked up. (See MEDICAL RECORD, April 13, 1918, page 654.)

The Selection of New Occupations for the Disabled.—Mr. T. B. KIDNER of the Department of Soldiers' Civil Re-establishment, Canada, spoke on this subject. He said that this problem was primarily medical and secondarily social and economic. In considering it, the condition of the labor market must always be taken into account. In choosing an occupation for a disabled man, three persons were involved, the medical specialist, an occupation counsellor, and the man himself. Such occupations must be selected as promised permanent employment and steady wages. The man's own choice was always consulted and he was always asked if he had a hobby, for that frequently gave an indication of the kind of employment into which he might be fitted. The man's intelligence was also noted and his previous industrial history taken. The possibility of giving him the opportunity of training for something higher than he had done before, as a profession, must be taken into account, if he showed the intelligence and desire for that. In the reconstruction school a record of each man's work was kept and report sent in each week, and if he did not fit in one place it was discovered and an effort made to place him in a more suitable vocation.

In Canada there were very few medical men who were trained in industrial medicine, but they were rapidly progressing in this respect and the American Industrial Physicians' and Surgeons' Association had done much during the past few years to stimulate an interest in health work among industrial workers. Another thing the National Office in Canada was doing was to keep follow-up records of every man who went through the reconstruction school. They kept in touch with these men, giving them advice and helping them to adjust themselves to their new occupation. They

felt that reconstruction work was worth while, not only from the point of view of the disabled man, but because it was a great saving to the Government in the long run.

The Results of Rehabilitation in Foreign Countries.—Mr. DOUGLAS C. MCMURTRIE of the Red Cross Institute for Cripples in New York delivered this address. He said that the subject of reconstruction had been so thoroughly covered by the previous speakers that it was becoming increasingly difficult to find a new phase of the subject upon which to discourse. The Red Cross Institute for Cripples in New York was founded because they had feared that the Government might be slower in starting this work, owing to the amount of red tape that was necessary in any governmental project, than a private agency would be. The school had been established from six to nine months and carried on various activities in the way of vocational training. It had already placed 600 men in employment and had carried on a research department which was going to be of great use. One of the first duties that confronted them was the collection of a library and the publication of a series of studies. It was felt that the only way to learn to deal with the cripple was to begin to deal with him, and that the industrial cripple needed reconstruction as much as the army cripple, so they began with him. This they had been doing, and though they had few army cripples they were ready for them. They would soon have a similar school in Chicago. The speaker then showed a motion picture film which was descriptive of the work done at the reconstruction school at Montpellier, France. There they taught cobbling, forging, coppersmithing, leather work, electrical work, and many other things. The manufacture of artificial limbs was an occupation carried on almost entirely by men who had lost one or more limbs. These men had a keen appreciation of the requirements of an artificial limb. They were also trained to repair artificial limbs, and this was a field of industry which would offer occupation to a good many men later on. Many men wanted to learn motor mechanics and automobile driving, but they discouraged them in this because the Army had now such a well-trained corps of motor drivers that would be looking for places after the war that they felt this field would be overcrowded. The important work to be done at the present time was to carry on an educational campaign to bring people to a sensible and intelligent knowledge of this work. For the past four or five months they had been trying to reach every one; they had sent folders to every minister and every physician, to chambers of commerce, and to employers of labor, so that the public generally might understand and assist in restoring the disabled both of the army and of industry to a life which would be as nearly normal as possible. They did not wish the employer to feel that he took these men and gave them work as an act of charity; they wanted the employer to know that these disabled men were being trained to give a labor value of one hundred cents on the dollar. In this work they were counting on the co-operation of the public and of the medical profession as well.

Colonel MOCK announced that he had just received a telegram from Washington informing him that the bill creating a Federal Board for the Reconstruction of Crippled Soldiers had been passed by Congress.

Mr. MONRO of Boston, the vice-president of the Federal Board of Vocational Rehabilitation, emphasized the need of changing the old attitude of the public which regarded the cripple as an object of charity and of no use except to be thrown on the scrap heap; instead of that, they wished to educate the public to regard the cripple as one of the economic pillars of society. The soldier's attitude when he woke up after his operation to find himself a cripple was one more or less of despair and hopelessness. Every soldier and sailor thus crippled would at first feel wretchedly discouraged and he would feel timid and sensitive in regard to his deformity. The first thing to be done was to inspire and hearten these men. Then the next thing was to overcome the skepticism of employers who it would be difficult, perhaps, to teach that the disabled men could be as useful from the economic standpoint as were the able-bodied men. The cripples must be saved from the

danger of being exploited as cheap labor. There would be hard times ahead after the speeding up demanded by the war was over and we should have to guard against the tendency to scrap the cripple first when the supply of labor became greater than the demand. All these things had to be overcome by educating the public. The schools and colleges of the countries and the industries themselves would have to take a part in this work of reconstruction. The crippled soldier was only incidentally a medical or a surgical problem; the final problem was that of making him not only physically a man, but socially and economically a man. Physical restoration of the disabled man was futile unless the man had the proper attitude toward society and industry and unless the industries were in a proper attitude toward these men. As soon as possible, while the men were still in the hospital, the effort should be made to awaken hope and ambition. In order to fully carry out the plans for social reconstruction of the disabled, the effort of the home towns should be enlisted in the social reinstatement of the returned soldier. It was essential that these men should be placed back in their home environment, and to this end it was advisable to have many small vocational schools throughout the country and to have the schools and colleges co-operate in giving vocational training.

Mr. LAKEMAN of the American Red Cross said the American Red Cross stood ready to supplement the work of the Federal authorities. The Red Cross was to-day quietly doing a great work among the families of the soldiers through its local committees and Home Service Section. To help the families of soldiers the Home Service Section provided a doctor and a lawyer so that the interests of the family were all looked after. The lawyer would look after the soldier's insurance, mortgages, etc., and everything would be done to preserve the solidarity of the family. When the disabled men were replaced in civil life the Red Cross would follow them up and there would always be a "big brother" ready to stand by him. The machinery for this work was already set up and the Red Cross eagerly waited to discharge its duty in this way.

Mr. MICHAEL J. DOWLING of Olivia, Minn., delivered an address in which he related how as a young man he was caught in a Minnesota blizzard, became lost, and had both hands and both feet frozen so that amputation was necessary. His resources were limited and he soon became an inmate of the poor house. There he remained for about two years, when he proposed to the authorities that if they would get him artificial legs and give him one year in college he would never again be a public charge. He had "made good" and was to-day a prosperous banker and an influential man. He said there was no machine for making successful men out of cripples. He feared that the well-intentioned scientific men were making a mistake in planning for too much mollycoddling, if he did not mistake the tenor and tone of some of the addresses he had listened to. What the cripple wanted was a chance, not pampering. In a nutshell, it was a fight between General Gorgas and general despondency. To the right kind of a man a handicap was an advantage. This country had been pampered too much and that was the reason it took us so long to get ready to clean up Germany. Another point to be emphasized was that the public should be taught not to notice deformity in a man. Every man with a deformity was sensitive about it. Ministers should teach from the pulpits and the school children should be taught in the schools not to notice a peg leg or an empty coat sleeve. The message he wished to bring from his personal experience was that there was as much in life for the crippled man as for anyone else.

A number of motion picture films were shown which were a part of the educational propaganda for disabled soldiers and which furnished example of the "Cheer up" work that was necessary in order to develop the proper mental attitude in the disabled soldier. They showed crippled men engaged in various occupations and in sports. These pictures demonstrated very convincingly that there was no need for despondency on the part of the disabled soldier provided he had the courage, the ambition, and the determination to be again a man among men.

Army Surgeons Promoted.—Dr. J. M. T. Finney and Dr. William S. Thayer, Chief Consultants of the Medical Service of the American Expeditionary Forces, have received promotions advancing their rank from Major to Colonel. The following named officers have been promoted from Major to Lieutenant-Colonel: Thomas R. Boggs, James T. Case, George W. Cole, Harvey Cushing, Joel W. Golthwait, James F. McKernon, Charles H. Peck, Thomas A. Salmon, Hugh H. Young, N. Allison and E. L. Keyes.

Request That Gift to Red Cross Be Used for Research.—The War Council of the American Red Cross has received a request from Cleveland H. Dodge, who has subscribed over a million dollars to the Second Red Cross War Fund, that \$250,000 of this sum be set aside for the investigation of methods for the prevention and cure of diseases to which our soldiers and sailors may be exposed. The Red Cross is anxious to have gifts specially designated for the purpose of research work so that no work of that kind requiring animal experimentation would be done except with money specially contributed for that purpose.

American Hospital Sacked by Turks.—The Presbyterian Board of Foreign Missions has identified a hospital recently sacked by Turkish troops at Tabriz, Persia, as the Colton Memorial Hospital. Dr. W. S. Vanneman of Salem, N. J., was the physician in charge.

Gas Hospital in Charge of Women Physicians.—A 300 bed hospital for gas cases has been assigned by the French Government to the Women's Overseas Hospital. The French Service de Santé will maintain the beds, but the National Woman Suffrage Association will supply the doctors and nurses. Another cable makes an urgent request for more doctors, nurses, and nurses' aids for an extension of the Labouheyre refugee unit. These two units together with two other units in France are being financed by the women suffragists of America.

Three Ambulances for France.—The Sons of the American Revolution, Empire State Society, in a meeting in New York City, on June 18, presented three ambulances to the Republic of France, through General V. Vignal, representative of Ambassador M. Jusserand. One of these ambulances is already at work on the front in France, another is on the way there, and a third will soon be sent.

A New War Disease.—According to a dispatch to the Associated Press the attention of British Army doctors has been attracted to an affection called "trench mouth." It is said that the disease first appeared in the German Army and that observers think it is caused by a prolonged diet of canned food.

Harlem Physicians Prepare for Air Raids.—Fifty Harlem physicians have organized for first aid treatment in the event of an air raid on New York City. They are undergoing preliminary training under Lieutenant A. Lustgarten of the United States Army Medical Corps, who is giving a thirty days' furlough to this work. Any physician desiring to volunteer his services in this work will be accepted.

ADRENAL INSUFFICIENCY IN SOLDIERS.

SATRE considers this subject in the *Journal de Médecine de Paris* for April in connection with actual campaigning troops. Under excessive action he would include nervous tachycardia and certain cases of death after craniocerebral wounds. Hypoepinephria is of course the antagonistic condition and a number of syndromes of this nature have been described. The tremendous overexertion of the warriors entails exhaustion of many organs, endocrinic or other. A campaign seems especially calculated to wear out the adrenals. Even before the war a component of adrenal insufficiency was reckoned on in various affections as typhoid fever, scarlet fever, diphtheria, chloroform anesthesia, etc. During convalescence of any kind there may be seen hypothermia, low arterial tension, and other evidences of adrenal insufficiency. Another such syndrome was apparent after gassing. Still another is visible in the shock which follows major wounds—in fact, Satre believes that shock, so called is *per se* very largely adrenal insufficiency.

Of especial interest is the part played by adrenal insufficiency in the accidents sometimes seen after antityphoid immunization. The vaccine may exert a special action upon this gland, as shown by animal experiment, and a considerable literature on the subject already exists. The proportion of these accidents is not large, being 1 to 400 or 500, and is quite independent of the species, mode of preparation, etc., of the various forms of reaction known, only that is understood which is purely suprarenal in character. In a case cited there developed three hours after the second puncture intense pain and tenderness in the epigastrium, agitation, subdelirium, headache, fever, etc. The pulse could not be counted and unfortunately no attempt was made to measure the pressure. At fifteen hours there developed convulsions and apoplectiform symptoms. There was no response of the pulse to camphorated oil. At twenty hours the patient was almost comatose, and vomited. Sergeant's white line was obtained on testing. Not until then was adrenalin injected, in repeated doses, and gradually the symptoms receded, and consciousness returned, the patient complaining of the severe headache and backache. He

received adrenalin injections for a long period, until completely recovered. In a second case the syndrome appeared after the second puncture in a very simple form—hypotonia and prostration. There was no cerebral reaction. After the third puncture, however, there was high fever, pulse rapid, tension 80, embryocardia, abolition of reflexes. The symptoms became worse and the tension fell to 65. There were profound sweats and diarrhea. Sergeant's white line was in evidence. The lumbo-abdominal pains of the first case were reproduced. Cyanosis and coldness of the surface were marked. The syndrome could have suggested an intense poisoning. There was constant hiccough. The tension fell to 60 and the white line was strikingly present. The patient was given oxygen subcutaneously and 1 mgm. of adrenalin. In half an hour the tension was up to 80. There was a constant tendency to swoon. Ether and camphor were also injected. Convulsions and delirium developed, although other symptoms improved. After the patient had received 8 mg. of adrenalin there were still severe pains in the trunk and head. The tension was now 95. Before termination of the case the patient had received 30 cg. of adrenalin and 10 of pituitrin. the tension was 125. Headache was the last symptom to leave. The duration of treatment was only three days. In both cases narrated the offending puncture was made after trench life, which appears to indicate that immunization should be completed before the men enter upon campaign hardships. It was noted by the Germans that protection often failed in immunizing men in the midst of campaign hardships.

ETIOLOGY OF TRENCH FOOT.

OF the novel medical affections arising from modern warfare, trench foot is perhaps the most interesting, although the factors that operate to cause the condition are still very obscure, and treatment is far from satisfactory. It is very much a question whether trench foot is a disease or a symptom of a disease remote from the site of manifestation. Naturally the external manifestations of this disease such as the edema, the skin infections, and even the gangrene have made plausible the theory that the disease is a local one imposed on the extremities as a result of trench life. Treatment necessarily has been local. Good results have, indeed, occurred rather from prophylactic than active treatment, through the better care of the feet frequent relief from trench duty, sufficient rest, the establishment of wash houses, etc. Some clue is obtained as to the probable cause of the condition by the similarity that it bears to Raynaud's disease, intermittent claudication, erythromelalgia, etc. In these diseases local causes cannot be found, yet the symptoms have some resemblance. In the latter diseases, disturbance of the vasomotor apparatus is believed to be the principal cause. In trench foot it seems now more than probable that the same in-

ternal causes, vasomotor in character, operate under provocation of the adversities of trench life.

Sweet, Norris, and Wilmer (No. 16, Phil. U. S. A. Gen. Hosp., B. E. F.) found clinical evidence in cases of trench foot to corroborate the theory that it was caused by vasomotor disturbance. They found a marked increase in the blood pressure of the leg as compared with the arm. This increase of blood pressure is caused either by an undue vasoconstriction or by a loss of the vasodilator power, and the first indication for treatment according to these findings would be some blood pressure reducing substance. There is this discrepancy in the theory that while the edema and diapedesis are due to effusion from the capillaries, the increase of pressure that might cause the diapedesis would occur in the arterioles and not in the capillaries. After the blood leaves the arterioles, on account of the greatly increased capacity of the capillaries the pressure therein is markedly reduced. The arterioles are probably where the greatest amount of resistance is encountered by the blood current. Besides, the arterioles have the vasomotor mechanism of change. Neither the veins nor the capillaries have this mechanism. On the other hand, the circulation in the veins and the capillaries is dependent upon initial conditions of the heart pressure, the action of the skeletal muscles, and the peripheral venous circulation. The mere standing for an excessive period will affect this surface circulation even to entire stoppage. The resort to continual motion and rubbing of the extremities recommended by way of prophylaxis in trench foot is based upon this consideration.

It can be said, therefore, that trench foot is excited by such trench conditions as dampness, cold, and long standing, but occurs only in men whose vasomotor apparatus is primarily impaired. The vasomotor spasm in trench foot is incomplete; were it complete the pressure thrown back to the heart would cause a neutralization, but being incomplete the pressure manifests itself only in the extremity, causing such symptoms as tingling, numbness, burning, pain, edema, and an ischemia of the parts affected. Swelling of the foot, and even gangrene, are final results. The difference in pressure between the arm and the leg is sometimes as much as 10 to 30 mm. of mercury, and when this difference has been reduced improvement is likely to follow.

THE SYMPTOMATOLOGY OF HEMORRHAGE IN HYDRONEPHROSES.

BESIDES those complications of hydronephrosis which are well known there is still another which is less familiar, namely, a hemorrhage taking place into the hydronephrotic sac. This complication is uncommon, and usually results from traumatism, but from this very fact malignant urohematonephroses, likewise those resulting from distention of the sac, cannot be excluded from the differential diag-

nosis. Urohematonephrosis varies greatly as to its beginning. The patient may have sustained a fall, or, on the other hand, the symptomatic phenomena may be insidious. There are no disturbances of the digestive apparatus until the time when the hydronephrotic sac has by its increased size encroached upon the abdominal viscera, and gastric symptoms occur from the resulting compression.

The early symptoms of this particular process are frankly indistinct; these patients are usually well built, without loss of weight, the pulse and temperature are normal, so that nothing indicates the true condition of affairs. The urinary symptoms are most varied. Occasionally the urohematonephrosis is intermittent, in which case the emission of bloodstained urine is merely temporary. On the other hand, the patient may not have any disturbance in the urinary functions, but a renal tumor will be found. The renal area will be found enlarged, extending to the thorax and abdomen in some instances. Or the abdomen may present a one-sided enlargement from the costal border to the iliac crest. A point important to note is that the integuments overlying the tumor are normal; there is no edema, and the venous dilatation is never at all marked.

Palpation may at times be difficult, and if care be not taken a diagnostic error can easily be made, particularly when following a traumatism which has given rise to urohematonephrosis; there is some infiltration of the cellular tissue, itself the result of the trauma. Percussion is of great importance, but the results must be properly interpreted. In most cases it is safe to say that the tumor will be found directly under the anterior abdominal parietes without visceral interposition, and the colon will be found near the midabdominal line.

If, now, one tries to decide upon the nature of the tumor, it will be first noticed that it is movable over the underlying surface, but that it is not movable transversely. A pedicle may be detected. Pressure over the tumor does not give rise to pain, but rather to discomfort, and a sensation of dragging in the corresponding testicle. Compression of the nervous plexuses by the tumor mass readily explains this phenomenon. The tumor may be apparently quite hard and even, but usually some amount of fluctuation can be made out. In some cases the tumor has been the source of very severe pain, the result of intracystic tension, which is at once relieved by a urohematic discharge, in every way similar to that occurring in intermittent hydronephrosis. After this, things quiet down, and the tumor decreases in size and pain subsides. In some cases the symptomatology has been thoracic, and the true condition of affairs is made out only after a very detailed examination. From the varied and rather deceitful symptomatology of urohematonephrosis it becomes evident that a correct diagnosis will be made only after a most painstaking examination of the patient, since in quite a good percentage of cases urinary symptoms, other than the occasional appearance of blood, are wanting.

TREATMENT OF CHANCROIDS AND THEIR BUBOES.

POIRSON, in charge of a venereal service in the French army, has published a Paris graduation thesis on this subject, an abstract of which appears in the *Journal de médecine et de chirurgie pratiques* for April 10. This treatment is extremely simple, recalling the old management of these lesions with ethereal solution of iodoform, but apparently more efficacious, and free from the telltale odor. A solution of sodium arsenate in alcohol, one part to fifty, is said to be so efficient that a single application may suffice. There is no preliminary cauterization. The first step in the management consists in cleansing the sores with tampons soaked in ether. The process is continued until not a trace of pus remains in evidence. The arsenate solution—or rather suspension, because the salt is poorly soluble in 95 per cent. alcohol—is shaken well and applied with a camel's-hair brush thoroughly to the sore or sores. In order to hasten the evaporation of the alcohol a jet of air may be blown upon the lesions. The arsenic is thus left upon the latter as a fine coating. Soon afterward a second application is made and a piece of sterile gauze is placed over it. In certain locations this dressing will have to be renewed often because it is worn away by secretions, etc. Even under unfavorable circumstances, from 3 to 5 dressings will turn the ulcers into simple raw surfaces, which heal rapidly of themselves. The author advises, however, the use of alternative applications until healing is complete, iodoform being a good dusting powder. Much of the efficacy of the treatment is thought to be due to the preliminary treatment with ether. If a bubo has formed, but without the immediate menace of suppuration, the author injects a solution of arsenic directly into the mass, the strength being one-half of the preceding. If pus has already formed, it is evacuated by puncture with a small trochar, which is also used to break down any septa in the pus cavity. The solution is then injected as before. In ulcerated chancroidal bubo the treatment does not depart from that of the chancroid. The author has treated 250 patients with his method, the average duration of treatment being 18 days for simple chancroid and bubo up to 29 days for complications.

News of the Week.

Move for Militarization of State Health Boards.—It is reported that the Surgeon General of the Army and his staff have given their approval to a plan, all the details of which have not yet been worked out, for the federalization of all State and, perhaps, all municipal health organizations. A conference on the plans was held in Washington on June 21.

Doctor Arrested for Using Seditious Language.—A physician, long resident in Mount Vernon, N. Y., and for many years a naturalized citizen of the United States, but born in Germany, has been arrested on a charge of sedition. The alleged seditious language is said to have been used in a Yonkers restaurant in the presence of a number of people.

Exposition of Chemical Industries.—The fourth National Exposition of Chemical Indus-

tries will be held in the Grand Central Palace, New York City, during the week of September 23, 1918. The advisory committee of the exposition announces that this will be the largest and most interesting chemical exposition ever held in this country. Among the exhibits of special interest will be examples of what the chemists of America has produced since the world war began. There will be in connection with the exhibition a series of symposiums on the Development of Chemical Industries in the United States.

Hospital Building Destroyed by Fire.—The hospital building of the Erie County Poorhouse was destroyed by fire on June 19. Fifty patients were carried to places of safety by the nurses. The loss is estimated at \$75,000.

Trial Brings Out Tale of Suffering Among Insane.—The trial of Freeholders who are under indictment for unhealthy conditions obtaining in the hospital for the insane at Overbrook, N. J., brings out the fact that there were 92 deaths in that institution during November, December, and January of last winter as compared with 35 for these months of the preceding winter. It was stated that most of the time during December and January the temperature of the wards was never above 28°. Other evidence also indicated that the inmates of the institution were subjected to much suffering and discomfort.

Fined for Hoarding Food.—A medical director in the Navy who was recently charged with unlawfully hoarding foodstuffs, has been tried in the Supreme Court of the District of Columbia, found guilty and fined the sum of \$1,000. It is said that part of the illegally stored food will be confiscated by the Government.

Yale University Meets Requirements.—Yale University Medical School has now met the requirements of the General Education Board and the \$2,500,000 endowment for the medical school is complete. The medical school will receive interest on the board's subscription of \$582,900 as a part of its yearly income.

Gifts and Bequests.—Columbia University and the Presbyterian Hospital each receive bequests of \$610,345 by the will of Kate Collins Brown.

The Loomis Sanitarium of Liberty, N. Y., and St. Mary's Free Hospital for Children, New York, each receive bequests of \$1,000 under the will of Mary M. Irwin.

The Ossining Hospital, Ossining, N. Y., is the recipient of a bequest of \$1,000 under the will of Mrs. Julia Greer Simmons.

Hospital Drops German Name.—The institution hitherto known as the German Hospital of Cleveland has decided to change its name and will be known as either the Franklin Avenue Hospital or the Fairview Hospital.

Disease Ravaging Roumania.—According to a report from Amsterdam, Roumania is negotiating with Germany for large quantities of drugs and other medical supplies to combat diseases growing out of the war conditions. It is said that disease is raging with disastrous results in Roumania and that the population in some districts has been decimated.

New York Medical College and Hospital for Women Closed.—Women physicians interested in

the New York Medical College and Hospital for Women, who recently protested against the action of the trustees of that institution in voting to close the college and disband the student body, after a conference with the Board of Regents, have decided to accept the action of the Board of Trustees inasmuch as women are now admitted to most of the general medical colleges throughout the country. Another reason for agreeing to the closing of the medical school is that they the women see in it the opportunity to gain control of their own hospital which contains 110 beds. They are starting a campaign to raise \$50,000 with the idea of using the hospital to care for wounded soldiers.

Obituary Notes.—Dr. VALENTINE MOTT died suddenly of angina pectoris at his home in New York, on June 20, aged 65 years. He was widely known as a surgeon, a traveler, and a writer. He was graduated from Columbia College in 1872, and from Bellevue Hospital Medical College in 1878. He also had a degree from Trinity College, Cambridge, England. Dr. Mott was appointed attending physician of the outdoor department of Bellevue Hospital in 1879, and in 1887 was sent to Paris as the representative of the American Pasteur Institute to study with Louis Pasteur. He was entrusted with the first inoculated rabbit that was permitted to leave the laboratory to be brought to America. Following his return to this country he wrote many treatises on the Pasteur treatment of rabies. He was the grandson of Valentine Mott, a famous surgeon of his day.

Major EUGENE WILSON CALDWELL of the Medical Reserve Corps of the United States Army died at the Roosevelt Hospital, New York, from the effects of x-ray burns received many years ago, on June 20, aged 48 years. Major Caldwell took the degree of B.S. from the University of Kansas in 1892, and was graduated from Bellevue Hospital Medical College in 1905. He did experimental work in marine telephone for the United States Lighthouse Board, and later was an assistant in the engineering department of the New York Telephone Company. He was visiting roentgenologist to the Presbyterian Hospital and roentgenologist to the German and Orthopedic hospitals. He was a member of the American Roentgen Ray Society, the American Medical Association, and the New York Academy of Medicine. Major Caldwell was the inventor of the Caldwell liquid interrupter, of special forms of Roentgen tubes, and of a number of other appliances that are used in x-ray work. He had only recently completed an appliance for stereoscopic fluoroscopy especially adapted to war needs.

Dr. FREDERICK WEYGANDT of Brooklyn died on June 12, aged 70 years. He was educated at the University of Worms, and graduated from the College of Physicians and Surgeons, New York, in 1875. He was connected with the Eastern District Hospital of Brooklyn.

Dr. JAMES R. BERWICK, a graduate of Yale University Medical Department, in 1899, died suddenly of heart disease at his home in Methuen, Mass., on June 1, aged 49 years.

Dr. HENRY W. LITTLETON of Badin died at the Charlotte Sanatorium, N. C., on June 10, aged 30 years. He was a recent graduate of Jefferson Medical College, Philadelphia, Pa.

Obituary.

WILLIAM MECKLENBURG POLK, M.D., LL.D.,
F.A.C.S.

NEW YORK.

Dr. WILLIAM M. POLK, one of the last of the older generation of gynecologists of this city, died in Atlantic City on Sunday, June 23. He was born in Ashwood, Tenn., on August 15, 1844, the son of Bishop, later General Polk, the "fighting bishop" in the Confederate Army. The younger Polk also served in the same army with the rank of captain. Very soon after the close of the war he came to New York to study medicine, and was graduated from the College of Physicians and Surgeons in 1869. From 1876 to 1879 he was professor of therapeutics in the Bellevue Hospital Medical College; from 1879-1898, professor of obstetrics and gynecology at the New York University Medical School; and since 1898 dean and professor of gynecology at the Cornell University Medical College.

Dr. Polk was gynecologist to Bellevue Hospital and consulting gynecologist to St. Luke's, St. Vincent's, and the New York Lying-in Hospitals, and to the New York Infirmary for Women and Children. He was a member of the New York Academy of Medicine, of which he was president from 1910 to 1914, of the New York Obstetrical Society, of which he was president in 1884, of the Medical Societies of the County and State of New York, of the American Medical Association, the American Gynecological Association, of which he was president in 1896, the Southern Surgical Society, the Southern Gynecological Association, and of various gynecological societies in England, France, and Belgium. He was a not infrequent contributor in his younger days to medical periodicals, and was the author of a biography of his father, entitled "Leonidas Polk, Bishop and General," published in 1894.

Correspondence.

THE PROPER FORM OF QUININE FOR CHILDREN.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: I read with interest Dr. Sheffield's very interesting article in the issue of the MEDICAL RECORD of June 22. I am rather surprised, however, to see him suggest bisulphate of quinine as a quinine salt for children. Being one of the most soluble of the quinine salts, it is naturally one of the most bitter; and it is quite cruel to give quinine bisulphate to children in solution. As to the extract of glycyrrhiza and syrup of acacia covering the taste of quinine in solutions, this is purely mythical. The licorice and the acacia add to the nauseousness of the mixture and take away very little of its bitterness. Even the quinine sulphate would be a much better salt to administer to children than quinine bisulphate, for while quinine bisulphate is soluble in about nine parts of water it requires about 725 parts to dissolve quinine sulphate. In other words, quinine sulphate is about 75 times less soluble in water than the bisulphate.

But there is a much better salt than either, namely, quinine carbonate, or the neutral carbonic

ester of quinine. That being absolutely insoluble, is absolutely tasteless, and may be administered to children without the least trouble. It can be given either dry on the tongue or rubbed up with milk sugar, or suspended in any aqueous or syrupy liquid. If Dr. Sheffield will try the neutral carbonate of quinine he will not say that "Disguise it as you may, quinine will taste after quinine as long as there is quinine in the mixture."

Quinine tannate and quinine salicylate are also practically tasteless, though they are to a minute extent soluble in water; when mixed with chocolate powder or chocolate syrup, the most fastidious and sensitive taste will fail to discover any bitterness. The quinine carbonate, however, is preferable, and, of course, in the stomach it is readily converted by the hydrochloric acid into a soluble quinine salt. So that there is no fear of lack of absorption.

WILLIAM J. ROBINSON, M.D.

NEW YORK.

OUR LONDON LETTER.

From Our London Correspondent

THE ORGANIZATION OF THE MEDICAL PROFESSION IN RESPECT OF THE WAR—POSITION OF THE STAFFS OF THE LONDON HOSPITALS—ORIENTAL DISEASES IN THE BRITISH ISLES—KINEPLASTIC AMPUTATIONS—TITULAR HONORS FOR DISTINGUISHED MEDICAL MEN—THE CASE OF DR. JOHN HENDERSON BELL.

LONDON, June 6, 1918.

THE position of the medical profession in this country, in general respect to man power and in particular regard to medicine, has again been undergoing revision at the hands of various Government departments. The situation is flattering for the profession but confusing in the multiplicity of regulations issued for our information. During this week, however, the Ministry of National Service has issued a statement to medical practitioners regarding the position of those liable under the Military Service Acts 1916 to 1918, which clears away certain difficulties, while introducing a new element into professional obligations. The age of compulsory medical service for doctors has now been raised to 55, as I have already reported (see MEDICAL RECORD, May 11, p. 820), and the Statutory Bodies entrusted with granting exemption, viz., the Central Medical War Committee, the Scottish Medical Service Emergency Committee, and the Committee of Reference of the English Royal Colleges, which had hitherto been advisory only, are now constituted the actual Tribunals by which applications for exemption are considered. The grounds for exemption are given as four: Physical ill-health, private disabilities, conscientious objection, and lastly, the needs of the civil community amidst which the medical man practises. Of course, the last is far the most important ground for appealing against conscription, and it is here that a new feature has been introduced, and it is here also that the Ministry of National Service comes to play a part in proceedings which have hitherto been conducted between the military authorities on the one hand and the medical practitioner on the other. (It has to be remembered that, while the words "military authorities" are used for brevity, they cover the Navy and the Air Force as well as the Army.)

Hitherto the practitioner was granted exemption because his professional work at home was considered to be of more importance to the State than any work that he could do as a medical officer in the Navy, Army or Air Force, while his combatant possibilities were not considered. If exemption was granted he remained in practice discharging public or private duties, as the case might be, in his own locality. But now, if exemption is granted, this means that, while he need not accept a Commission in the medical service either of the Navy, Army or Air Force, neither need he necessarily remain at his previous occupation. For the Ministry of National Service has a lien upon him, and may find that in the national interests it is more expedient for him not to continue to practise at his home, but rather to undertake such civilian medical work as the Ministry, in consultation with one of the Statutory Bodies, or in concert with any Government Department, may determine in his respect. The new development is not viewed with general approval by the medical profession. For example, the Edinburgh Branch of the British Medical Association has registered through its Council a distinct disapproval of the move. They protest against the exercise of any power over a medical man to compel him to undertake some new work in civil practice to which he may have serious and valid objections, and they hold the view that many of the medical men who may be treated in this manner are exactly the people perfectly able to act as military medical officers at home, giving thereby an opportunity to younger and stronger men to serve abroad.

The honorary staffs of all the hospitals of the London area are coming in for a special piece of organization at the hands of the Statutory Body particularly concerned with the question of their exemption, viz., the Committee of Reference. With the approval of the Minister of National Service who is playing a part here also, it has been decided that the staffs of the hospitals in the metropolitan area shall be arranged in new groups, whereby, while a sufficient service is reserved for each group, more medical men will be set free to join the Army. It is a fact that in a huge place like London many members of hospital staffs waste much time in long journeys to and from their work, while similar work, and much more of it, could be done by them at institutions nearer to their doors. How far this is constituting a waste of material will be discovered by an analysis now being undertaken by the Committee of Reference. When the detailed work of every member of the staff of the metropolitan hospitals is set down in tabular form it should be possible to decide what number of doctors possessing the qualifications generally held by the medical officers of hospitals are indispensable to the civil community. From among this number all the hospitals of the metropolitan area will for the future have to be staffed, discontinuing, perhaps, their services at their former institution and being transferred to another one. The surplus medical officers will be offered commissions in the Navy, Army, or air force, the Army having, of course, far the greatest need. This scheme of reorganization has been actually set on foot. It is recognized that it will cause great inconvenience to the medical men concerned, as well as to the Governors and

officers of the various hospitals, but the patriotism of all concerned is being relied upon.

British Medical Officers in Turkish Prison Camps.—The treatment of British prisoners in Germany has been horrible, but in Turkey a far higher standard of humanity has been reached. Turkish civilization has not the same material possibilities to offer as the German authorities could provide if they chose; but Turkey appears to do her best by her prisoners. It is now arranged that one British medical officer and five medical personnel of other ranks should be detained in Turkey per 1,000 British prisoners, the agreement being that the Turkish authorities will make a suitable distribution of their medical staff among the prison camps.

In times of peace the world-wide trade from British ports made it necessary for the port authorities to keep anxious watch upon arriving ships lest Oriental diseases should be introduced into this country. The value of the precautions taken at large ports like those of London, Glasgow, Leith, Hull, and Bristol has been many times shown, especially in regard to plague, a disease which has been most obstinate in its attempts to regain its medieval hold over Europe. The war has added to these risks immensely in one direction, while only slightly modifying them in others. Despite U-boat activities the trade of Great Britain remains enormous, and the risk that the population may, through commercial channels, be affected with Oriental diseases remains practically unaltered, but simultaneously we have the transmission to and fro between Arabia, Mesopotamia, India and East Africa of thousands of men who have either been in contact with Oriental diseases or in relation with contacts. The vigilance of port medical officers, and of the military officers detailed to assist them, has been of the greatest value to the country, and no cases of Oriental diseases have remained undetected on British shores for more than a few hours. It is probable, however, that in the future more may be heard and seen of various forms of Leishmaniasis and "oriental sore" among British troops returning home from India, Mesopotamia, and the Mediterranean seaboard. With regard to plague, the proceedings adopted are those in accord with the International Sanitary Convention of Paris in 1912, when the disease is found on board an arriving vessel. The ship remains moored in the river, the cargo is discharged bale by bale from deck into lighters, after which the ship is disinfected by methods which must result in the destruction of the rats, to whom no opportunity has been given for leaving the ship. All the crew and passengers on the ship after medical inspection are subjected to the quarantine regulations of the country. In this way there is little risk of the spread of plague among the British population; but plague is now a well-understood disease, whose symptoms are readily detected. More risk is really run in rarer forms of disorder, and the responsibility as port officer of health is distinctly heavy.

At a recent meeting of the Royal Society of Medicine Professor Putti, director of the Rizzoli Institute of Bologna, expounded the theory and practice of kineplastics to an interested meeting, whom he convinced that the conception of kinematization contained enormous possibilities for the future of

badly disabled men. The term kineplastics stands for the technique by which amputation flaps are constructed having a power of independent movement. The original exponent of the methods was Dr. Giuliano Van Ghetti and his experiments were originally suggested by his endeavors some 20 years ago to remedy the deformities among the Italian prisoners who had been mutilated in the course of the Italian war with Abyssinia some 20 years ago. In Italy, in Austria, and to some extent in Germany and Switzerland, kineplastics have been worked at during the interval, but Prof. Putti had right on his side when he called attention to the fact that in the United States, France, and England, little attention was paid to an important scientific innovation, namely, the possibility of full utilization of the functional resources of a stump. The application of kinematization entails a wholesale neglect of the previous methods of amputation, as muscular insertions, skin flaps and tendons, which would not only have been superfluous but mischievous if left in the course of an ordinary amputation, become the scaffolding on which the motor machinery of prosthesis is to be erected. The direction of incisions and the preservation of bony surfaces have also to be carefully observed, if the greatest recovery of motor power for the patient is to be obtained. The ardent advocates of kineplastics would consider that even at the First Aid Dressing Station the surgeon should operate so as to leave a fair field in the immediate future for kineplastic methods. This, of course, entails a general knowledge of the method and its aims and objects and a natural or acquired aptitude on the part of the operator in performing his contribution to the final success of the operation. These methods have now been applied to arm and thigh stumps with great success. In the forearm, for example, living terminal motors, one contrived with the tendons of the flexor muscles and the other with the tendons of the extensor muscles, form two kinds of "fingers" under complete voluntary control, and the contractions of these "fingers" can be transmitted to an artificial hand through metal rings covered with vulcanized rubber. The result is that the subject can give dissociated flexor and extensor movements to an artificial hand. The mechanical attachments appear to be remarkably tolerated, the rings playing through elaborately prepared tunnels in the muscles. What has been so successfully done in the forearm stumps has been proved possible in other directions, and there seems no doubt that the whole technique is capable of great development. Researches at the Rizzoli Institute show that the preparation of motor flaps is a well-defined surgical technique, and there is now sufficient experience on record to make it certain that many surgeons will try to work along the lines where Italian surgeons have been brilliant pioneers.

Dr. H. D. Rolleston, now a surgeon-general in the Royal Navy, and the learned collaborator with Clifford Allbutt in the "System of Medicine," has been made a K.C.B.; Colonel A. W. Mayo Robson, formerly vice-president of the Royal College of Surgeons of England and a famous pioneer in abdominal surgery, has been knighted; and a K.C.M.G. has been given to Colonel W. H. Horrocks, a leading exponent of military sanitation and a member

of the Advisory Board of the A.M.S. since the outbreak of war.

Dr. John Henderson Bell, a medical man of high standing and unblemished record, was condemned last year to serve a sentence of six months' imprisonment for a supposed "act preparatory to an act" to enable a soldier to evade military service. The circumstances in which the conviction was secured made all medical men, and those laymen who gave the facts and allegations close attention, perfectly certain that Dr. Bell was an entirely innocent man; and now the General Medical Council, at the summer session just expired, have shown this to be their official view of the case by confirming Dr. Bell in his legal status as a medical man, and retaining his name on the Medical Register. The evidence against Dr. Bell was suspect from beginning to end. The chief witness was a deserter who had left France with another man's papers, and the supporting testimony was given by a policeman, who set a trap for Dr. Bell with the assistance of other people, to one of whom a sum of money was paid! The actual facts of the case, though not disclosed in so many words at the trial, have become apparent. An intending malingerer had given money to somebody, who had received it on the understanding that it should be devoted to obtaining for him medical assistance to escape the army orders. The man who had received the money had to do something in return for it, and the something that he did was to represent to Dr. Bell that the patient required ordinary treatment, while informing the malingerer that the treatment which he was about to receive was given him with the object of enabling him to escape military obligations. Then the malingerer became a police informant, and then the police, having made up their minds that they had a real case, proceeded with any sort of evidence to secure a conviction rather than admit the error into which they had fallen. There was never any evidence that Dr. Bell received excessive payment for his medical treatment of the individual who laid information against him, while the treatment that was administered was properly directed to the condition in which the man was represented to be. The miscarriage of justice was assisted by the general air of prejudice diffused throughout the proceedings; an appeal failed, and Dr. Bell served six months' imprisonment, although surprise was manifested that there was no remission of the sentence, the *Lancet* stating definitely that the conviction was a miscarriage of justice, and other journals being critical of the legal procedure. The view that has now been taken by the General Medical Council to the common pleasure of the medical profession is that the conviction was wrongly secured, and the Council is the disciplinary body of the profession, and itself a standing committee of the Privy Council. By the General Medical Council a register of the medical profession is maintained at a proper professional standard, they remove from the list the names of all (to quote the awkward phraseology of the Act of Parliament) "who have been guilty of infamous conduct in a professional respect," as well as all those who have undergone, or who are undergoing, legal sentence for a criminal offense. If the General Medical Council had not believed in the inno-

cence of Dr. Bell, his conviction would *ipso facto* have ensured his removal from the list. The Council have departed from precedent and have retained his name, and Dr. Bell is thus recognized, in the public as well as in the professional eye, as a victim of a breakdown in the legal machinery of his country. There is a grave moral and physical debt owing to him which cannot be paid, but there is one side of the position where Dr. Bell can be assisted. His attempts to defend himself cost him a large sum of money—£800 or more, and I believe it is the intention of Dr. Bell's professional brethren to start a subscription in his behalf.

4. Pathological Classifications of Pulmonary Tuberculosis. Herbert F. Gammons.
5. Idiopathic Epilepsy a Sympathicopathy. Edward A. Tracy.

4. Pathological Classifications of Pulmonary Tuberculosis.—Herbert F. Gammons points out that pulmonary tuberculosis may be divided, according to its pathology, into inflammatory and ulcerative types, and that these types may be subdivided into fibro-inflammatory or fibro-ulcerative of the incipient, moderately advanced, or advanced stage, according to the other manifestations of the disease. Diagnosis may be made clinically by stethoscopic examination and also by observation of the sputum and the use of the x-ray. As a rule, the inflammatory cases have bronchovesicular, or, in some instances, bronchial breathing, depending upon the site of the lesion; other cases show fine rales of a crepitant nature. The ulcerative case shows muco-purulent or purulent sputum with elastic tissue fibers, and stethoscopic examination demonstrates signs of cavitation, including marked variation in the vesicular respiration, increased sound transmission, and rales of a mucous character, depending upon the stage of the ulceration. X-ray examination shows all degrees of shadows, depending on the stage of the ulceration, while in simple inflammatory cases it has been negative. A faint shadow surrounding a deeper shadow usually means active inflammation in the faint, shadowy area which is surrounding an old fibroid or ulcerative process that gave the darker shadow. The treatment of these different pathological conditions varies for each type. For instance, a simple inflammatory incipient case does not need the rest that other types require. The moderately advanced ulcerative case often needs more rest than the advanced fibro-inflammatory case without constitutional symptoms. The prognosis depends to a certain extent upon treatment; the far-advanced case of the fibro-inflammatory type, with its acquired resistance, will often do better and live longer, with proper treatment than the active inflammatory type of the incipient stage. Gammons believes that by using the present classification of Rathburn, and adding the pathological type, it may be possible to give the patient more definite advice as regards prognosis and treatment of his disease.

5. The Treatment of Leg Ulcers. P. G. Skillern.
6. Preparation of Solutions of Salvarsan and Arsenobenzol for Intravenous Use. Herman Goodman.

3. Clinical Significance of Intestinal Hemorrhage.—Frank C. Yeomans points out that in every obscure case of intestinal bleeding the blood should be examined and a Wassermann test made. A leucocytosis suggests an inflammatory process, while eosinophilia may be a clue to intestinal parasites. The hemoglobin percentage and the red cell count are indices to the degree of anemia, and the morphology of the cells indicates whether the anemia is primary or secondary. In children, bleeding may be due to (1) partial or complete prolapse of the rectum, (2) polyp or multiple adenomata, (3) prolapse of the sigmoid into the rectum. In adults, hemorrhoids are the most frequent cause of bleeding, and the tendency of the lay mind is to ascribe all cases of bleeding to this cause. The danger here lies in overlooking other causes, and for this reason no case of bleeding piles should be submitted to operation before proctoscopy. Bleeding from hemorrhoids occurs in a rather copious hemorrhage at long intervals, which is often due to rupture of an overdilated vein from cirrhosis of the liver and as a safety valve in relieving portal congestion does not require treatment unless the hemorrhage is excessive; a spurting stream of blood from a single ulcerated pile; or a constant daily ooze. In the two last cases anemia results, and they should be considered as possible causes of secondary anemias. In the case of thrombotic external hemorrhoids a simple excision under local anesthesia usually ends the trouble; but if neglected these may lead to fistula, with its possible sequelæ—spasmodic sphincter, constipation, and alimentary toxemia, or abscess followed by fissure, or reflex symptoms referable to other organs or to the nervous system. Pain accompanying hemorrhoids usually denotes a fissure, which must be differentiated from other lesions, such as blind internal fistula, chancre, condylomata, tuberculous ulceration and epithelioma. Then again there is the bleeding from ulcerative proctitis and colitis, and here hemorrhagic colitis should be given special mention. This is a rare condition, which has been studied only comparatively recently, and which is probably of infective origin. The main symptoms are loss of weight, weakness, anemia, and diarrhea, with many foul passages, ten to twenty daily, containing some mucus and pus, but mostly blood. The proctoscope shows a typical bosselated mucosa, exuding blood freely. The entire colon is involved and sometimes all its coats. Prolapse of the rectum, partial or complete, occurs in adults as well as children; bleeding is less frequent, however, and its source is to be recognized only by instrumental examination. A polyp in the terminal ileum may be the exciting cause. Thrombosed varicose veins also may give rise to an alarming hemorrhage. Embolism of the mesenteric arteries is a very grave, and usually fatal, condition associated with endocarditis and valvular disease or atheroma of the aorta, while thrombosis may be due to a local endarteritis, calcareous glands, or injury. The only histological difference between polypi in children and multiple adenomata in adults is the greater proportion of glandular tissue in adults and of connective tissue in children. Histologically, these tumors are benign; clinically, without suitable treatment they become malignant in two to three years in about 50 per cent. of cases. Large, solitary, adenomatous growths of the sigmoid and rectum are of clinical interest because of the severe symptoms to which they give rise, and their liability to malignant transformation. The author reports a case of solitary polyp of the rectum in a gentleman aged seventy-six years which became an adenocarcinoma, a case of papillary adenoma, and one of adenomyoma of the rectovaginal septum in which the leading symptom was melena. Of malignant tumors, sarcoma of the rectum practically never occurs, while in the colon it is rare; on the other hand, carcinoma is very common. There is, unfortunately, no one symptom or group of symptoms characteristic of early cancer of the colon or rectum, but in a large series in one-third of all cases of cancer of the large bowel the passage of blood was the first symptom. Yeomans concludes with a mention of certain obscure causes of hemorrhage and with the warning that until a diagnosis has been made and definite indications for surgical intervention have developed it will be very much safer to employ expectant measures than to operate.

3. A Bacterial Toxin as the Cause of Retinal Hemorrhage.—F. Park Lewis reports a case of retinal hemorrhage which was caused by the *Streptococcus hemolyticus*. The hemorrhages had occurred over a period of eight months, in spite of treatment. Pyorrhea was present, and roentgenograms showed that there were apical abscesses of several teeth with rarification of alveolar tissue. The infected teeth were removed and the infecting organism found to be the *Streptococcus hemolyticus*. Removal of the source of infection was followed by a cessation of the hemorrhage. In a subsequent case of recurrent hemorrhage an infected tooth was suspected of being the focus of infection. This was found to be so, and the *Streptococcus hemolyticus* again isolated. The author adds that since then, in almost every case of hemorrhage of the eyeball, some form of focal infection has been found, and the active organism has usually been the streptococcus, almost invariably the *Streptococcus hemolyticus*. The hemorrhage is not the result of force from behind, but is due to softening of the tissues of the capillary or arterial walls by the local action of the toxin, thereby producing lysis. Lewis points out that this conception has not heretofore been recognized as a cause of retinal hemorrhage. The importance of the subject is evident; it establishes a definite etiology, satisfactorily explains many pathologic changes otherwise obscure, and gives specific methods of procedure which may have a preventive value in conditions endangering sight, or even life itself. The author shows from a discussion of the literature that our fundamental knowledge of the cause of retinal hemorrhage is exceedingly indefinite. It has been generally assumed that the internal pressure becomes so great that it can no longer be resisted by the retaining wall of the blood vessel, which consequently ruptures, or that the vessel wall becomes so weakened that the normal pressure can no longer be resisted. Lewis points out, however, that little attention has been given to the manner in which structural changes take place, or on what they are dependent; on this point our whole conception of the actual etiology and, therefore, prognosis and treatment is based. He believes that a soluble protein poison which is given off from the focal infection is absorbed into the blood and has a solvent effect on the intercellular cement substance of the cell wall; and that the hemorrhage is not due to alteration of the blood pressure but to local lysis in the wall itself. It is known that several varieties of toxins given off by as many different bacteria are capable of producing hemorrhage; the effect, indeed, is not dissimilar to that of the snake venoms, which Flexner has shown contain a chemical substance which has a definite endotheliotoxic action on the intercellular substance. As to changes of blood pressure, Lewis points out that the force is practically negligible by the time it reaches the capillary terminals. The importance of this subject is more manifest when it is considered in relation to hemorrhages in other parts of the body in addition to those of the eye. In cerebral apoplexy, for instance, it is very doubtful whether the vessel breaks from internal pressure of the blood, but more likely the protein poison has so affected the nutrition of the endothelium that the normal elastic cellular substance is so softened that dissolution of the walls results and hemorrhage is precipitated.

3. On the Physiology of "Functional Paralysis" of "Voluntary" Movement, with a Description of a Case of Inversion of the Kinesthetic Sensations.—Captains T. Graham Brown and R. M. Stewart discuss an interesting case of "functional paralysis" which resulted from a severe shock by lightning. On the twenty-fifth day—extensor rigidity being present—the patient was placed under chloroform narcosis and the objective motor phenomena carefully studied. At a certain depth of narcosis the patient was able to move the left limb; he was made to continue this movement while narcosis was diminished, and when perfectly conscious was shown that he was using his limb normally. This procedure was repeated and the patient made to move the left arm in the same way. He was then put to bed and given opium. He moved the limb freely during sleep, and upon awakening was able to move it readily. Left hemianesthesia and hemianalgesia persisted. There was a curious reversal of kinesthetic sensations, which, however, was quickly corrected by training. In this case the paralysis did not appear immediately after the shock, but succeeded a slowly spreading numbness. The paralysis was at first a flaccid one, but was succeeded by a state in which the limbs showed rigidity. As long as the kinesthetic sensations remained absent the return of "voluntary" power to the left limb was slow. The arm was usually held in a rigid position. The gait was "functional." When under a certain form of treatment, "voluntary" movements were much improved; this improvement was almost at once accompanied by reappearance of appreciation of kinesthetic sensations, and when once this had reappeared a further and rapid improvement of the "voluntary" movements occurred. However, failure of appreciation still persisted for movements at joints of left toes and fingers, and (to a less extent) for movements of left ankle and wrist; and it was at these joints that the "voluntary" movements were least fully established. Captains Brown and Stewart point out that "functional paralysis" is often accompanied by functional disturbances (depression) of sensation, and that the functional paralysis of a limb is almost always accompanied by anesthesia or analgesia of that limb. The "motor" mechanism of the cerebral cortex becomes inactive in that part of it which is cut off from the centripetal (sensory) nerve impulses of the part of the body the movements of which it subserves, but the mechanism itself remains a workable one. They suggest that the so-called "functional paralysis" is secondary to the anesthesia, a view which is supported in the case described by the fact that the paralysis appeared after the numbness, and persisted in those parts in which the kinesthetic sensations were absent longest. They offer in explanation of the cases in which the paralysis persists after resolution of the anesthesia, the suggestion that long disuse of the cortical mechanism may have rendered it relatively inexcitable to the impulses which normally play upon it. These observers next take up the question of "functional gait." In the act of progression two main types may be recognized, the phasic and the postural. Cortical reactions are characterized by their phasic nature; those of the red nucleus by their postural. The authors are of the opinion that "functional paralysis" is probably due to an abnormal exaggeration of a normal manner (postural) of holding and moving the limbs. This manner has been facilitated by use,

whereas the subject is conditioned by a relative difficulty in activating the cerebral (phasic) mechanism, which in turn is conditioned by the failure of certain centripetal (sensory) impulses to rise above the threshold of the cortical motor mechanism, a failure which is conditioned by some other factor. The "postural" state is, as it were, a bad habit. The obvious treatment, therefore, is one which lowers the threshold of the cortical mechanism, and, of course, should be undertaken as early as possible. This can perhaps be done by increasing the value of the impulses which play upon it—the authors ask, Is this how suggestion works?—and, when the mechanism becomes activated by them, by facilitating the mechanism by practice. However, in the view of the authors, the primary condition is the anesthesia, and when this is resolved the cortical mechanism will also be facilitated by the playing upon it of impulses which are ineffective in the state of "functional paralysis." (Does suggestion also play a part here by increasing the intensity of these impulses until they cross the motor threshold and then lower it constantly by their passage?) In any case, the authors wish to emphasize that in such cases of "functional paralysis" the most striking thing, the gait and the postural movements of the limbs, are probably but the symptom of a symptom, and must be treated as such.

1. The Bacterial Flora of War Wounds: Influence of Treatment.—Sir Kenneth Goadby gives the results of his observations on the bacterial flora of wounds carried out on convoy cases arriving at English hospitals since the commencement of the war. Routine bacteriological examinations were conducted throughout in a uniform manner. During the winter of 1914-15 a large number of spore-bearing organisms were found; these were of the following types: (1) Bacilli with a central spore, staining deeply by Gram's method; (2) bacilli containing a subterminal spore; (3) bacilli with a rounded or oval end spore. The presence of these organisms became less frequent during 1916, and in the latter part of 1917 they were only observed in limited numbers. During the first two years Gram-negative bacilli belonging to the coli and proteus groups were frequently met with, but the incidence, especially of the proteus group, later diminished. During the first half of 1916 there was an apparent diminution in the number of sporing anaerobes isolated from wounds, but from that period to the end of 1917 the incidence rose steeply. A considerable rise also occurred in the number of proteolytic and saccharolytic organisms in the second half of 1916. Sir Kenneth Goadby therefore points out that though the mass infection has diminished progressively from 1915 to the present time the persistence of anaerobic bacteria has not undergone similar quantitative reduction. He also states that no great diminution in anaerobic flora has been effected by the use of the two antiseptics of which statistics have been available (bipp and hypochlorite); that latent infection, as opposed to persistent infection, is of great importance in "subsequent operations," and that latent infection is determined by the treatment of the case in the first week of the injury, possibly in the first three days; that in latent infection organisms are found in close proximity to healthy tissue, and therefore in a region likely to become the site of an incision in a subsequent operation; that bone fragments split off at the original injury invariably become sequestra, probably due to the proteolytic action of the bacteria rather than to destruction of blood supply;

that of the various methods which have so far been made use of in the immediate treatment of wounds immediate excision of the lacerated tissues is apparently the only one that has produced a marked diminution in the anaerobic flora of the wounds.

3. The Alleged Cure of Leprosy.—Cabrera denies any specificity in the so-called Garcia plan for the treatment of leprosy, which consists in the ingestion of certain herbs in order to make chaulmoogra more tolerable to the stomach. The method is antiquated, as the author maintains that nowadays the best way to give chaulmoogra is hypodermically or intravenously.

6. How Should the Oculist Proceed in Hopeless Cases?—Juan Santos Fernandez recommends that some caution should be observed in dealing with the hopeless blind. The diagnosis of total and irremediable blindness should be withheld for some time, and only given out after one is sure the case is such and the patient can bear to hear the truth. In the case of well-to-do people there is no such necessity of telling them their unfortunate condition as there is in poor people, who need reeducation in order to be able to support themselves.

Berliner klinische Wochenschrift.

April 8, 1918

Pulmonary Resection.—M. Zondek relates the history of a patient who received a bullet wound in the right thoracic cavity. A pulmonary fistula resulted, this being followed by a series of empyemata, which did not give way to drainage or various forms of irrigation. Finally Zondek decided to undertake a more radical interference. After having done an extensive thoracotomy, he freed the lung from all adhesions, peeled off the fibrous layers adherent to the lung and then resected the pulmonary parenchyma surrounding the fistula. A large cavity resulted which was closed by sutures. Later on a cutaneous flap operation was done to close the thoracic wound. The patient made a good recovery. Passing to general considerations of the subject, Zondek studies the distribution of the bronchial tubes since in resection of the lung, the operation must depend upon their anatomic arrangement which is as follows: the bronchi form cones with the apex directed towards the hilum; the base is oval in shape, the great axis being anteroposterior in direction, that of the lesser axis being vertical. As to operative indications, the writer mentions pulmonary fistula, especially when the pleural cavity is filled with adhesions. Resection is less to be recommended in cases of neoplasms, tuberculosis, extensive bronchial dilatation, and multiple pulmonary abscesses. Lastly, the writer insists upon the advantages derived from pulmonary amputation which ensues after removal of the atelectatic tissue and fibrous layers which fill the pleural cavity. (For a very complete paper on this subject the reviewer would call attention to: Roux-Berger et Policard, Plaies de Poitrine, *Lyon Chirurgical*, No. 6, 1917.)

Münchener medizinische Wochenschrift.

April 2, 1918.

Clinical Symptomatology of Alcapsonuria.—E. Epstein recalls that this affection is due to the elimination of homogentisin acid in the urine. This is a hydro-

quinone-acetic acid derived from tyrosin and phenylalanin by reactions which are almost all known. The writer has observed two brothers afflicted with this disturbance of the metabolism. Besides the dysuria which brought the patients to seek medical advice, the writer calls attention to the peculiar coloring of the cartilages of the ear, likewise that of the integuments of the face and pigmentation of the sclerotic. This ochronosis is found at autopsy of these cases. The cartilages are colored brown, while the joints even undergo changes, giving rise to osteoarthritis deformans. The writer particularly insists on the possibility of making the diagnosis simply from the clinical findings and case history.

Continued Rhythmical Spasm in Cerebral Foci.—H. Klien has observed three cases of lesion of the cerebral substance of the hemispheres in which spasms occurred in the muscles of the pharynx, larynx, and even the diaphragm. He concludes that there is a homolateral cerebellar localization exercising a permanent action on the centers of deglutition, respiration, and bulbar nuclei. The writer has met with a case of descending degeneration of the cerebello-olivary tracts, which has been considered until now as an ascending process.

The Treatment of Pulmonary Tuberculosis by Isolated Partial Antigens and by a Mixture of These Antigens.

—G. Deycke and E. Altstaldt are opposed to the views of W. Müller, and point out the fact that tuberculous cases in general react more to the fatty than to the albumin antigens, contrary to Müller's findings, which distinguish from this viewpoint, between pulmonary and surgical tuberculosis.

Revue Médicale de la Suisse romande.

February 1918.

Four Cases of Obliteration of the Superior Vena Cava.—Faure refers to obliteration from thrombophlebitis and the pioneer article on the subject, by Oulmont, 1855, which comprises an account of 19 cases reported between 1808-1852 of obstruction of this vessel. Of this number but three seem to have been due to primary phlebitis. The great majority were the result of compression from without or destruction of the vessel, and since 1852 numerous cases of the latter have accumulated in contrast to a very meager number of cases of primary obstructive phlebitis. The author has had the rare good fortune of seeing four cases of this most rare condition—almost equal in number to the entire sum of the cases on record—for only such cases are included as are reported in some detail with autopsy finds. No case before Oulmont's time is included, so that but five authentic cases had appeared prior to the present author's report, viz.: Oulmont (1855), Comby (1892), Achard (1896), Benda (1908), and Bonninger (date not given). The author's four cases, which made a grand total of nine, were all seen in the Geneva Medical Clinic between 1908 and 1915. The nature of the author's cases throws some light on our want of knowledge of this condition, which in the author's material, at least, was frankly syphilitic. Not all the cases have the same mechanism, however, for in addition to specific thrombophlebitis it is possible for a gumma to involve the perivascular tissues and cause a form of secondary phlebitis. In any case, these conditions are amenable to specific treatment, which may account in part for their great rarity. A third mechanism is seen in the compression of the superior cava by syphilitic aneurysm of the aorta. This appears to have been present in the author's third case. The first and fourth cases were examples of primary phlebitis, while the second was due to extension of specific mediastinitis.

Treatment of Amebic Dysentery by Enemata of Salvarsan.—Calame has tested this new resource, unaware, perhaps, of its employment by others. Two cases of typical dysentery are reported in one of which emetine was quite efficacious, in association with applications through the proctoscope, of nitrate of silver solution. The second case, however, proved quite refractory to all treatment. The author, before resorting to appendicostomy, gave enemata of salvarsan, apparently because he had obtained good results in rectal ulceration of ambiguous nature by these means. The results were surprising in the prompt amelioration obtained, and the patient was soon pronounced cured.

AMERICAN MEDICAL ASSOCIATION.

Sixty-ninth Annual Meeting, Held in Chicago, June 10-14, 1918.

(Special Report to the MEDICAL RECORD.)

(Continued from page 1114.)

SECTION ON SURGERY.

First day—Wednesday, June 12.

DR. E. STARR JUDD OF ROCHESTER, MINN., IN THE CHAIR.

Congenital Cleft Palate and Harelip.—Dr. TRUMAN W. BROPHY of Chicago presented fifteen forms of cleft palate which were considered as follows: Embryologically speaking the defect arose from failure of the primitive structures to close. They were always present, never absent. After birth the deformity was increased by subsequent lack of muscular development. It varied from a slight to a marked degree. The main etiological influence was heredity; if the defect was not seen in the immediate family, it certainly could be traced to progenitors, being definitely atavistic in nature. Prenatal influences were considered negative. Defective intra-uterine influence may have had some effect. Supernumerary teeth and faulty invagination of mucous membrane were believed to be important factors. Venereal and uterine infections were not underestimated. Some of the exciting causes were believed to be: the disproportion of the tongue to the mouth cavity in the embryo; in the uterus in a vertex presentation, where there was a marked flexion of occiput, the mandible was pressed against the maxilla. Operation must correct not only the deformity, but also restore phonation. Operation was indicated as early as possible, one month after birth being a good time. An underfed child must have its nutrition attended to. The author's rubber palate dam allowed perfect deglutition. Colds and other constitutional symptoms and mouth infections should be treated and cured before operation; as to operation—bone surgery was absolutely essential. First the bones must be united and held in normal position by non-absorbable sutures, silver wire and lead plates. The latter relaxes the tension on all tissues. The premaxillary bones were never removed as they were essential for the formation of features.

The maxillary bones were considered ununited fractures, hence to be approximated and immobilized. The second step, six weeks later, consisted in closing the lips. At the third step the soft palate was closed. The result of these operations produced a functional normality of deglutition and phonation. If operations were performed in later life, proper phonation was difficult and it was best to have a new language taught. The author strongly urged the necessity of a more thorough teaching of this subject in the medical colleges.

Dr. S. J. OCHSNER of Chicago compared this operation to the old Ferguson and Lannenbach procedures. He commented upon their crudeness and Dr. Brophy's improvement upon their technique, as well as his detailed study from embryological and other broad standpoints, and again laid emphasis upon the fact that cleft palate was not due to loss of tissue, and that if the palate was merely a cosmetic and not a functioning one, the procedure was a failure and better results were obtained with an artificial palate. Also he urged re-education, and in cases of long standing it was best to teach a new language.

Sir ARBUTHNOT LANE of England, did not agree in all points. He stated there was actual loss of substances in marked cases. He advocated early operation, and stated that he used the flap method. Infants at this age did not mind operation, and stood shock very well. He advocated the flap operation, and stated that a similar operation was performed in the war zone for maxillary injuries.

Dr. CHARLES H. MAYO of Rochester gave a detailed description of the causation of anatomical anomalies. He stated that anomalies were natural in lower types of life in passage from a unicellular to a multi-cellular organism; from the invertebrate to the vertebrate, and

that they were readily produced, experimentally, in certain vertebrates.

Dr. J. ROBERTS of Philadelphia stated that he borrowed part of Sir Arbuthnot Lane's and part of Dr. Brophy's technique, and that both had their special indications.

Dr. T. W. BROPHY of Chicago, in conclusion, stated that in Sir Arbuthnot Lane's technique the mucous membrane was brought in contact with the muco-periosteum, whereas in his method denuded bone was approximated with denuded bone.

The Principles of Thyroid Surgery.—Dr. CHARLES H. MAYO of Rochester stated that the thyroid gland was one of the endocrines first noticed, owing to its anatomical position. In the treatment of this gland, surgery was the last resort, and then only when obstruction to respiration and circulation existed. He reviewed the rapid progress and surgical success of the operative procedures in the past few years. Tissue, analogous to the thyroid, existed in the substance of the tongue in 3 of 12,000 cases. The pyramidal lobe was struck out at times. The blood supply of the gland was such that all the blood of the body passed through the gland in one hour. The action of secretion depended upon a hormone. He cited Plummer and Kendall's chemical studies showing that the gland contained 65 per cent. iodine content. Kendall in 1915 isolated a substance composed of an organic nucleus with indol and oxygen; thyroid oxy-indol-iodine, which increased the power of secretion. Plummer had shown that energy was controlled by this substance and that hypo and hyper-thyroidism depended upon the amount of this substance present in the individual—that approximately 15 milligrams was normal for the whole body, and a slight increase quickened excitability and metabolic rate. Since the amount bore no relation to the size of the gland, recurrence of symptoms after partial thyroidectomies have occurred. Very often the gland extended to the thoracic cavity, hence the value of x-ray examination. Laryngoscopic examination before operation was advised. It was best to leave some gland substance to the posterior capsule in order to avoid parathyroid injury or removal. The lower collar incision was the best exposure. He cited 70 per cent. cures.

Temporary Loss of Voice Following Thyroidectomy.—Dr. DONALD GUTHRIE of Sayre stated the principal causes for loss of voice following thyroidectomy to be: 1. Trauma to the inferior laryngeal nerves. 2. Trauma to the trachea and larynx. 3. Lues. 4. Hysteria. (1) Trauma to the nerves was generally caused by the clamping of blood vessels in a pool of blood. Stretching of nerves caused post-operative edema. If the non-vascular zone of Crile was observed this was avoided. Rough sponging and handling of tissue was objectionable. A ligated nerve caused absolute loss of voice. A blood clot caused pressure on nerve. (2) Trauma to trachea by delivery of the gland from above downwards if the gland was very adherent to the trachea, that portion of it was left which produced the undue traction. (3) Hysteria and (4) lues—emphasis was laid upon pre-operative laryngoscopic examination, as if partial paralysis already existed a guarded prognosis could, and should be given. In reference to adductor and abductor paralysis, the former always suggested hysteria; the latter luetic infection often followed by beneficial results when potassium iodine was given. In the hysterical type great stress was laid upon the psychological treatment which varied from subconscious suggestion under anesthesia to active hypnosis. At times months of treatment was required to cure the hysterical condition. A case of Dr. Judd's was cited in which the patient supposed an adhesion existed, which was finally cured by anesthesia and gentle neck massage.

Goiter in the Southeast.—Dr. EDWARD G. JONES of Atlanta reported a personal study of 400 cases of goiter and stated the incidence in the Southeast of the several types of goiter departed in no significant way from the incidence in other areas where thyroid troubles were not definitely endemic. He grouped them as follows: (1) Hyperplastic and toxic. (2) Non-toxic. (3) Non-hyperplastic and non-toxic. (4) Doubtful. He stated that 60 per cent of all goiters were listed as non-toxic; excluding from consideration the symptomless goiters of puberty, and that 64 per cent of the non-toxic goiters

were adenomas. Goiter in this territory was relatively rare; the colored race exhibited less tendency to thyroid pathology than did the white race; men are less frequently affected than published figures indicate; the occurrence of non-toxic goiters in families was suggestive, but not significant; no particular water supply was under suspicion. There appeared in this series no significant relation between pelvic disease and thyroid pathology. Maximum double resection in diffuse enlargements of the thyroid gland was advised, while in old people ligation of the thyroid arteries or injection of hot water was the procedure followed. The author has had no post-operative hypothyroid symptoms, but one aphonic case and no post-operative tetany.

Dr. DOWD of New York opened the discussion. He stated that Dr. Jones' statistical deductions were different from those in New York, where Graves' cases were in the majority. He considered Kendall and Plummer's adrenalin tests a good guide before operation. In New York the percentage of goiter in negro was much higher than in Dr. Jones' series of cases.

Sir ARBUTHNOT LANE of England advocated intestinal resection for certain forms of goiter as this method of procedure cured the condition. He was not so successful in the exophthalmic type.

Dr. M. O. PORTER advised removal of a permanent goiter as this condition, if not already toxic, would become so.

Dr. R. C. DUGAN of Chicago advocated the use of hot water injection in old and feeble cases with good results.

Dr. CHARLES H. MAYO of Rochester in closing remarked that gross myxoedematous and other hypothyroid types were often overlooked, because the supply of the secretion remained in the body 18 to 21 days after removal of the gland, which prevented immediate onset of symptoms. With the new laboratory methods the energy can be tested to an exact degree in these cases. The activating agent was more than the iodine content of the secretion. In answer to Sir A. Lane he stated that if the intestines really caused the thyroid enlargement, then only was an intestinal resection indicated.

Dr. GUTHRIE of Sayre discussed some of the anatomical anomalies of the blood vessels to the recurrent laryngeal nerve, and also spoke of the hysterical aphonia and its diagnosis.

Dr. JONES of Atlanta spoke of the value of the following test in the diagnosis of goiter. The injection of 15 minims of adrenalin would produce a greater rise in blood pressure, pulse, and tremors at times in a case of goiter than in a normal case.

Glycophilia.—Dr. WILLY MEYER of New York stated that at the Lenox Hill Hospital, New York City, arrangements were made last February in the service of the author for the reception of a limited number of cases of the so-called thromboangitis obliterans for the purpose of examining the blood and other body fluids by every known method. When sugar was tested for, a distinctive type of hyperglycemia was disclosed to follow upon the ingestion of 100 grams of glucose. These observations were made by Dr. S. Bernhard, pathological chemist of the hospital. In fifteen cases thus far examined, the same result appeared with such regularity that this chemical test had become a reliable method of diagnosing the disease. The findings gave added strength to the theory of the writer that the disease was primarily not one of the blood vessels but of the blood, probably of endocrine origin—adrenals in conjunction with the parathyroids and hypophysis. The name "glycophilia" was tentatively proposed on the basis of this theory. The similarity of the name to hemophilia was intended to point to sex limitation and other obscure features of the disease. Characteristic of the condition of glycophiliacs when first seen seemed to be dehydration of tissues. This condition suggested the therapy: saturation of tissues with fluid by cumulative action with intensive combination treatment of duodenal flushing and hypodermoclysis sometimes yielded the desired result. The diluted blood entered channels from which it had been excluded by its great viscosity. Ischemic pains might have subsided. Pulsations now and then reappeared in the course of the short treatment in seemingly occluded arteries. Amputations were made peripheral and it was hoped with greater and more frequent success. The treatment de-

scribed above was palliative. The cure was hoped for as soon as the real cause of this mysterious disease was found. A mild antidiabetic diet was suggested to the patients and they were requested to return from time to time for a blood test. Cooperation and a well-endowed commission was recommended for the future study of this interesting condition.

Dr. SCHRAGER of Chicago pointed out the association of pes planus. He also spoke in favor of Oppenheim's theory of the congenital smallness of the blood vessels and how Ringer's solution benefited certain cases. The epigastric spasm associated with this condition simulated gastric crisis.

Dr. MEYER of New York stated the superficial gangrene required immediate treatment. He again emphasized copious flushing of the system and cooperation in the further study of this condition.

End Results in Hodgkin's Disease.—Dr. RALPH E. MORTER of Milwaukee reported ninety-three cases, including those reported by Dr. J. L. Yates of Milwaukee prior to July, 1917, with additional cases. Sixty-three of these were reported by Yates and Bunting, the same treatment being carried out at present as described by them in the literature of previous years. Hodgkin's disease and a group of allied affections were considered a non-communicable infectious granulomatous process due to the *Bacillus hodgkini* and partook in effect of the destructive potentialities of both a malign infection and a neoplasm. The treatment prescribed was the detection and elimination of a portal or portals of entry followed by complete and extensive surgical removal of as much accessible pathological tissue as circumstances permitted, aimed to rapidly replace the balance of power on the side of individual resistance. All surgical procedures were promptly followed with x-ray and repeated from time to time. The x-ray was considered a valuable adjunct to the treatment if applied judiciously. The dosage and application were measured by frequent blood counts, the actual lymphocyte curve was the index. Immune serum was employed routinely in all cases and more uniform and better results were apparently obtained with its use than without. General hygiene and prolonged rest were employed to maintain results, no special form of medication proved of any value; tonics and the like were the only drugs used. Apparently there was a fairly distinct line separating a possibly curable and an incurable condition in Hodgkin's disease. On one side, which was curable, there was apparent absence of demonstrable deep involvements; on the other side, incurable, its presence. In the potentially curable group there were twenty-six cases reported. The fifth successive year of clinical freedom from all evidence of disease as the earliest period upon which to base any valid claims of recovery was taken. Seven cases were reported as such. Two are of ten years' duration since inception, one of nine, two of eight, one of seven, and one of six. One case, duration five years, fell in the three to four years' period; two, duration two and one-half and three and one-half years, in the two to three-year period; five cases, duration two to four years, in the one to two-year period. Periods of freedom of one year or less were of no prognostic evidence. Of these twenty cases, apparently the only types where recovery was possible, there were five deaths, one of which discontinued treatment and one refused to begin, gave an actual mortality rate of less than 12 per cent. to date and a fair estimate of severity to 80 per cent. as the probabilities of recovery. In the later cases, except where lethally involved, much can be done in the way of prolongation of life and comfort, life having been prolonged in one instance eight years, the interim between a potentially curable condition and a hopeless widespread invasion might be only comparatively short. This accentuated to the utmost the importance of early diagnosis and treatment. To obtain lasting results it was necessary to follow the patient for years with approximate treatments until the blood picture returned to normal. The paramount factor was early diagnosis followed by adequate treatment. Hodgkin's disease, if taken reasonably early and vigorously treated, was not necessarily fatal.

Dr. LA PENTA of Indianapolis stated that diagnosis was not easy and many mistakes were made in early diagnosis. There was no typical blood picture and the

Bacillus hodgkini did not follow Koch's laws. Complement fixation and agglutination reaction were negative. He stated that Rosenow isolated a strain of streptococcus.

Dr. W. C. McCARTHY of Rochester pointed out here allied similarity of this disease to tuberculosis and lymphosarcoma in certain stages.

Dr. MORTER of Milwaukee, in conclusion, believed that this condition was produced by the *Bacillus hodgkini* and that positive agglutination in part was obtained with a positive result by one of his co-workers.

Chairman's Address; Surgery of the Gall-Bladder and Biliary Ducts.—Dr. E. STARR JUDD of Rochester, Minn., considered the general circulation a portal of entrance for infections of the biliary passages. When infection of the appendix, duodenum and gall-bladder existed at the same time, it was difficult to decide whether there was a primary source of infection or a common one. During the operation all the organs should be carefully explored so as to determine if there was an involvement of more than one structure; infection was most common in the gall-bladder; evidence of malignancy was very rare. Varieties of biliary disease: (1) Chronic cholecystitis—histological picture was not definite; pain was atypical; jaundice was not common; it was noted that in a number of cases neuritis developed. Cholecystitis preexposed to gallstones, which were only formed after certain types of infection. The gall-bladder was apparently normal at times; more frequently, however, it was white and thickened and did not empty on pressure. Gangrene and rupture had occurred at times without the formation of stones. The lymphatics were softened and enlarged. In those cases where the gall-bladder appeared normal its removal was found advisable, as drainage was insufficient to prevent recurrence. (2) Cholelithiasis—The pain was colicky in nature; there weren't any symptoms of jaundice or fever. Here again it was noted that the gall-bladder was normal at times but was most often thickened and inflamed, in various degrees. Drainage of the gall-bladder was not considered sufficient treatment, as many stones were overlooked and reformed in the course of three to six years; therefore cholecystectomy was advised. (3) Stones in the Common Duct—In this type of case cholangitis, fever and jaundice existed, the gall-bladder was contracted, frequent distention of which caused pain. In all cases the ducts were explored for stones which if found were removed and the biliary ducts drained. (4) Jaundice—In this group of cases there was a painless jaundice and the diagnosis was difficult without an exploratory operation, as the symptom was produced by one of the following conditions: cirrhosis of the liver, pressure of the head of the pancreas, etc. (5) Stones in Common Duct Without Pain—In this type of case the patient was always in a poor condition; if the jaundice was very marked, waiting was advised until it subsided; oozing and hemorrhage complicated the condition and added greatly to the mortality; hence the necessity for transfusion in these cases. In cases where oozing occurred during the first week the abdomen was reopened and trocar and cannula inserted into the liver, which greatly relieved the pressure on the liver cells, with a subsequent flow of bile. Saline irrigations were found to relieve liver congestion. Mann in a series of experiments removed the gall-bladder in dogs and arrived at the following conclusions: The gall-bladder was not a reservoir, but it secreted mucus which made the bile less irritating to the pancreas. The gall-bladder regulated the flow of bile. Operative technique on the biliary apparatus—Cholecystectomy gave the best end results. The cystic duct was secured with or without the artery; complete isolation of the cystic duct was essential to avoid injury to the common duct. It was not found necessary to remove all of the cystic duct. The common duct was only opened when stones were palpable.

Reconstruction of the Common Duct from the Experimental Standpoint.—Dr. J. SHELTON HORSLEY of Richmond, Va., reviewed some of the experimental work that has been performed in reconstruction of the common bile duct. He reported sixteen experiments of his own in which he had used a segment of everted vein. The experiment showed that while the duct was reconstructed in this manner it contracted after a month; eventually occlusion occurred. Photomicrographs of

the layer of transplanted tissue that came in contact with the bile showed infiltration with round cells and inflammatory products, and eventually contraction had taken place. There seemed to be a biological law of immunity of tissue around the lining of the bile ducts, bowel and urinary apparatus which made such tissue partly immune from irritating effects of their discharges. Attention was called to the fact that contraction was not prevented by having an epithelium lining, as contraction was due to the tissue underneath the epithelium and not to the epithelium itself. The continual irritation from irritating discharges killed some cells and injured others and so called for much more hyperemia and scar tissue than clear cut mechanical injury. For this reason and on account of the fact that tissues at some distance from the bile duct were not immune to these discharges, he believed that the best permanent result was to be obtained in reconstructing the bile duct by uniting the mobilized mucosa of the duodenum to the stump of hepatic or common duct.

Clinical Report on the Reconstruction of the Common and Hepatic Ducts.—Dr. LEGRAND GUERRY of Columbia, S. C., stated that surgeons were occasionally forced to reconstruct the common duct. He reviewed some of the procedures and stated that experimental problems on animals were not always applicable in humans and that the plan herein devised was not original. He referred to Dr. W. J. Mayo's reconstruction operation. The reasons for operation were: (1) Permanent obstruction at head of pancreas. (2) Inflammatory stricture of common duct. (3) Common duct divided during cholecystectomy. During a cholecystectomy the observation was made that the juncture of the hepatic and the cystic ducts which formed the common duct was not a fixed one. Numerous anatomical anomalies were cited to prove this point. The three essential things that were accomplished by the operation were as follows: (1) Where duodenum was closely bound by adhesions its mobilization was most important as he was enabled thereby to effect the anastomosis with greater accuracy. (2) This depended on the first and in turn mobilized the mucosa of the duodenum that when the suture line was completed the mucosa and submucosa of the duodenum was directly united to the light structures of the hepatic duct, producing a continuous epithelial line, and contracture in all probability would not occur. (3) To avoid subsequent contracture, as was pointed out by Dr. Horsley in preceding paper. In this operation submucosa covering existed, the absence of which bore the same relation to contraction of the anastomosis as the corium did to a burn of the skin. The corium caused the contracture in the skin and the absence of a proper submucosa a contraction following anastomosis between common ducts and duodenum. In conclusion the author stated that this method was not the only way of remedying these defects in the bile passages and in some cases not suitable, but that the plan had a sound surgical and physiological basis.

Dr. ARTHUR SULLIVAN reviewed the various reconstruction operations, including Dr. Horsley's and Guerry's operations and their defects, together with his own where a rubber tube was used and the anastomosis performed around it. He stated he has had excellent results with this operation and that the epithelium will grow and bridge a gap if sufficient mucous membrane was not present for direct anastomosis; there was less shock attached to this operation and material for the reconstruction was always handy.

Dr. CARL N. DAVIS used several different methods, but he was in favor of the tube method of Sullivan. He brought out the fact that stricture was present at the site of incision of ducts and he tried an oblique incision in cutting duct, but no difference in the result was obtained in the end.

Dr. McCARTHY of Chicago was also in favor of the rubber tube repair. He used a longer tube with the idea that it took a greater time to be expelled by peristaltic movement, hence giving the anastomosis a greater time for healing.

Dr. MARCEY of Boston gave a brief review of biliary surgery and stated that the operative procedures were American and devised by American surgeons. He also was in favor of a long tube in biliary duct repair.

Dr. STRAUSS of Chicago cited his experimental work

with fascial reconstructions, and stated the success of the operation depended upon technical skill.

Dr. HORSLEY pointed out the advantage of the Sullivan operation, namely, that the tissue in the biliary neighborhood was used which was most ideal and had a natural immunity.

The Role of the Cystic Duct in Recurring Cholecystitis.—Dr. J. EARL ELSE of Portland, Ore., read this paper. He said the cystic duct had three layers—an inner mucous, a middle muscularis, and an outer fibrous. Projecting into the duct were semilunar-shaped valves, known as the Heisterian valves. These were broader, taller, and closer together at the upper end. They contained circular muscular fibers as well as the ends of longitudinal fibers belonging to the muscular layer. Mucous glands extended from the surface of the mucosa into the deeper layers. The lesions of the cystic duct were classified as: (1) obstructive, under which were the intrinsic, or those lying in or extending into the lumen, the intramural, or those involving the walls of the duct, and the extrinsic, or those lying outside; and (2) the processes which harbored infection, which were best classified as intrinsic, or those in which the organisms grew within the lumen, and intramural, or those in which the organisms were harbored within the walls of the duct. Of the obstructive lesions, he dealt especially with the pathology of the Heisterian valves, which sometimes became markedly enlarged, obstructing the duct. Of the processes harboring infection, he dealt principally with the changes in the mucous glands, showing that these became infected and distended so that they were a menace, both through organisms going into the cystic duct and up to the gall-bladder, and organisms going into the general circulation and producing infection elsewhere. Clinically, he classified the lesions as those producing transitory complete obstruction, permanent complete obstruction, transitory partial obstruction, permanent partial obstruction, and those which served as a focus of infection.

The Ultimate Results of Chronic and Subacute Pancreatitis.—Dr. EDWARD W. ARCHIBALD of Montreal, Canada, presented this paper, discussing pancreatitis from a clinical and experimental standpoint. (1) Clinically, the longer the drainage of the biliary passages the better were the chances for a cure of pancreatitis; if the drainage tube was removed too soon a recurrence of pancreatic symptoms returned. At least four weeks' drainage was advised, the length of time, of course, varying with the individual case. (2) Experimentally, general opinion believed, somewhat loosely, that pancreatitis was due to gallstones, and that in particular bile was forced into the pancreatic duct presumably by impaction of gallstones in the ampulla of Vater. It was obvious that the majority of cases clinically did not allow of such an assumption by reason of their being no stones present, or of stones confined in the gall-bladder. The author several years ago demonstrated that the pancreas could be flooded with a solution running into the gall-bladder through a cannula under a known hydrostatic pressure. The sphincter described by Opie was found to be easily set in spasm by rapid use of pressure in the biliary system or by application of acid to the duodenal mucosa. In experiments resumed this year, using bile from the ox and the human, sometimes infected, sometimes including mucin, sometimes freed from colloid constituents, the author was able to produce several types of pancreatitis. Consequently he was able to assert that many cases of pancreatitis in the human must be due to a disordered action, probably spasm of the sphincter of the common duct acting so as to force bile into the pancreas. It was observed that the underlying cause may frequently consist in hyperacidity in the first portion of the duodenum, with or without duodenal ulcer. Prolonged fasting, alcoholism, gastric and duodenal ulcer, hyperchlohydria, on the one hand; on the other, alteration in the bile in the way of inflammatory blockage of the cystic duct represented the probable clinical basis for the occurrence of pancreatitis.

Dr. W. HAGGARD stated that he had had cases where the removal of the gall-bladder resulted in the cure of pancreatitis.

Dr. JUDG of Rochester cited evidence of W. J. Mayo in favor of removal of gall-bladder in pancreatitis. Also a case of drainage of gall-bladder with return of symp-

toms after drain was removed and recurrence after second and third drainage, and finally cured after gall-bladder was removed.

Second Day—Friday, June 14.

The Therapeutics of Tetanus.—Dr. HERMAN B. GLENNER of New Orleans reviewed 350 cases of tetanus from the records of the Charity Hospital in New Orleans. A comparative mortality was shown under the different forms of treatment receiving serum hypodermically, intravenously, intraneurally, intraspinally, and intramuscularly, for those treated with sedatives only, including chloralton, for those treated with sedatives excluding chloralton; and lastly, a few cases treated with magnesium sulphate. The magnesium sulphate treatment was given in a few cases without any striking results. Sedatives when given made patients more comfortable. The mortality was compared with that of the period preceding the serum treatment, showing that the serum treatment was without question the one of choice and that there was a very large decrease in the mortality of the disease. A plea for the use of larger prophylactic doses and the importance of frequently repeating the dose was insisted upon.

Dr. MELTZER of New York strongly advocated the use of magnesium sulphate and gave a brief review of cases so treated with excellent results. He stated that there were at least four strains of the tetanus bacillus and that the present antitetanic serum only contained one of them, hence the lack of uniform results. The great value of magnesium sulphate in making the patient comfortable.

Dr. HUNTINGTON, who visited army hospitals in Italy, stated that ten times the normal dose of 1,500 units were given, and that the mortality was reduced to one-tenth of what it was before large doses were given. The giving of large doses was routine in his clinic. He cited cases where 61,000 units were given. Dr. Meltzer was asked how to administer the dosage of magnesium sulphate.

Dr. W. E. LEE of Philadelphia stated, regardless of Dr. Meltzer's success with magnesium sulphate, the great value of the prophylactic dose of antitetanic serum and cited several instances in the present war: the marked decrease of tetanus where serum had been given and the marked increase where serum was not available for use.

Dr. HOLBROOK cited several cases in which he had used tetanus in conjunction with magnesium sulphate with good results.

The Use of Dichloramine-T and Other Antiseptics in War Surgery.—Dr. W. ESTELL LEE of Philadelphia stated that dichloramine-T had been found to be a germicide which possessed to an unusual degree properties which made it possible to meet the conditions which Dunham said governed the success of disinfection: (1) mass, (2) time (3) contact. (1) Mass—The irritation which accompanied the use of most germicides, limiting their use and governing their permissible concentration, was negligible, with dichloramine-T, which could be used in solutions as strong as 10 per cent., the germicidal mass of such a concentration being forty times that of a 5 per cent. solution of hypochlorite. (2) Time—Because of its peculiar stability in oil solutions and unusual speed of disinfection, the required time of contact with the infecting organisms was readily maintained. Under average conditions its germicidal activity lasted about eighteen hours, in contrast to the thirty to sixty minutes of Dakin's hypochlorite solution. Dunham had found that its speed was eight times that of the hypochlorite, 800 times that of a 1 to 1,000 solution of bichloride of mercury, and at least 2,880 times that of a 2 per cent. solution of carbolic acid. (3) Contact—The development of a mechanical method to obtain in infected wounds the all-important contact between this agent and the infecting organism was entrusted to the writers by Dr. Dakin. At the present time records have been obtained from 18,700 completed cases in civil surgical practice which have been treated with this agent in different places. After this fifteen months' work, with a total of 18,700 cases, we feel that the use of dichloramine-T has definitely improved the results we have obtained in the primary closure of traumatic wounds of the soft tissues, bones, and joints; that in the treatment of superficial accessible surgical infection

the use of dichloramine-T has uniformly given us better results than any other germicide we have employed, and that the method of its application was simpler and the dressings more economical than with any of the other chlorine agents. That the best results with dichloramine-T were only obtained when actual chemical contact of the germicide with the infecting organism was maintained. To maintain such contact in superficial surgical infections was a simple matter, and in the last few months of the work a satisfactory technique for this class of wounds was developed. In deep and inaccessible infections the problem was more difficult and the greater part of these fifteen months were devoted to this aspect. Our confidence in the germicidal value of dichloramine-T had so developed that when it did not control infections we believed that the chemical contact had not been maintained. The mass of the germicide employed had not been sufficient or adequate surgical treatment had not been given. The striking intoxicating effect of the chlorine group of germicides, which has become common knowledge through the general use of Dakin's hypochlorite solution, was just as satisfactorily exhibited with dichloramine-T.

Dr. EDWARD OCHSNER gave a brief historic review of the present and past antiseptic days, showed how each antiseptic had its day, and then the false over-enthusiasm removed the good points from many antiseptics which have almost fallen into disuse. He complimented the author on his conservative statements and in closing said that each antiseptic—bichloride, carbolic, or vaccine—had a special attraction for some specific organism.

Dr. F. B. TURCK of New York brought out his views on the destruction of tissue causing devitalization and autolysis with a subsequent formation of a toxic protein which caused death. Dichloramine-T, he stated, furthered the destruction of tissue and this point should not be lost sight of in the treatment of wounds. He illustrated these phenomena with lantern slides.

Dr. LEE thought Dr. Ochsner's outline very interesting. He stated that Lord Lister's idea was to prevent and not cause infections. He believed in part in the specificity of antiseptics for infection and stated in conclusion that the immediate removal of foreign bodies and devitalized tissue was just as important as antiseptics in the treatment of wounds.

The Hodgen Extension Suspension Splint and Its Simplification in Both Civil and War Surgery.—Dr. FRANK G. NIFONG of Columbia, Mo., stated that during our Civil War a wire cradle extension suspension splint was devised by Dr. John Hodgen, a great Western surgeon, which had never been excelled. The recent and most successful methods of treating fractures of the femur had incorporated the most essential principles involved in the Hodgen splint. A close study of the mechanical and anatomical factors involved demonstrated how peculiarly applicable was this type of splint to the lower extremity. It was devised by Dr. Hodgen as a war splint for the treatment of compound and gunshot fractures but had proven equally as applicable in civil practice, where most fractures of the femur were simple ones. The relative value of the several principles of treatment varied with the kind and site of fracture to be treated, age, environment, etc. Immobilization of the seat of fracture was of first importance. Extension and counterextension was absolutely the most essential and important of all factors of treatment. Suspension was peculiarly valuable in compound fractures where treatment of wounds was desired. The mobility of the limb and the patient were of much consequence. Physiological flexion at the joint made far better functional results. The Hodgen splint was superior and excelled other devices because (1) It immobilized the site of fracture satisfactorily; (2) It gave any required degree of extension with counterextension. (3) Abduction and adduction and varying positions were secured as the case demanded. (4) Extension was not from a fixed point but within the splint mobile. (5) Physiological flexion of knee was secured, preventing hyperextension and muscle strain with consequent bad fusion or paralysis later. (6) It left the patient freely mobile and the thigh as well, which made comfort for the patient and promoted recovery. (7) Suspension of the limb was obtained which was especially valuable in treating compound fractures, making drainage, irrigations, and dress-

ings easy. (8) It was an open splint allowing for inspection, massage and care of soft parts which were factors of much value. (9) It was a splint easily modified and forces were applied to meet the indications for treatment of any fracture from the pelvis to the foot. (10) A modification herein shown may not be excelled as a transport splint for war service.

Dr. WOOD of New Arkansas stated he was a student of Dr. Hodgen 48 years ago. He was in accord with what Dr. Nifong had said and demonstrated a modified Hodgen splint which was applicable to fractures of the upper extremity. The position of pronation and supination were made possible when the indication arose.

Dr. H. EISENDRATH of Chicago stated the Hodgen splint was an ideal war splint. He also spoke in favor of the Bucks' extension apparatus. The failures in using the latter were due to faulty applications. He absolutely condemned the plaster cast and agreed in general with Dr. Nifong's principles of flexion of limb. Extension of leg was not on the fragments but the fascia and intermuscular septor encircling the fragments.

Dr. REIDER of St. Louis stated the successful treatment of fracture of femur depended on good common sense treatment. He reviewed the history of fractures and splint in part and concluded by saying that muscular relaxation and contraction was the main principle in the treatment.

Dr. MOORE of Minnesota endorsed the Hodgen splint.

Dr. SANDERS of Tennessee stated that the Hodgen splint was of great value in old people where plaster cast and Bucks' extension were contraindicated, and its greatness rested in its simplicity.

Dr. NIFONG, in conclusion, was gratified by the discussions. He again emphasized that the extension was made by fascia lata and intermuscular septa and there should be just as much tension so as to allow the fragments to unite properly, and that it was especially used in old age to prevent bed sores and static pneumonia.

The Fall of the Alkaline Reserve Under Surgical Conditions: Its Effects and Prevention.—Dr. HOWARD W. HAGGARD of New Haven, Conn., presented various conceptions or theories of alkaline reserve, the difference between the alkaline reserve of metabolic diseases and that of surgical cases. The study in the latter had been sadly neglected. The alveolar CO₂ tension determined the factor in surgical conditions. Several interesting problems from the experimental surgical standpoints were presented. The alkaline reserve was increased by CO₂ inhalations; lowered by traumatism. If it fell below a certain point death was inevitable, and there were no known methods at present of restoring it. Certain variations in venous arterial and blood plasma occurred and the respiratory rate, character, etc., had a definite control over the alkaline reserve, through its CO₂ coefficient. An ideal anesthetic by the open method was therefore not always the best. By devising a method of inhalation of proper gaseous interchanges in respiration with a constant CO₂ factor, the maleffects of low carbon dioxide levels on temperature, oxygen consumption, venous return, arterial pressure, and intestinal peristalsis could be avoided.

Dr. TURCK of New York stated that the study of alkaline reserve was a great piece of American work, but as applied by Dr. Haggard in surgical shock overlooked the fundamental principle of the condition and only treated a symptom of shock. He again stated his conception of devitalization of tissue and formation of toxic proteose which was the only factor to be considered—this was the causation of shock.

Dr. HAGGARD stated that the theories advanced by Dr. Turck were taken up by European experimentalists and after extensive studies were abandoned. How CO₂ would prevent autolysis was hard for the author to understand.

Gastropostosis: Its Cause, Prevention and Cure with Special Reference to the Duret-Rovsing Operation.—Dr. GEORGE M. KREIDER of Springfield, Ill., stated that Glenard's paper in 1881 was a classic and opened a new era in medicine, and that his observations were based on palpation and percussion of the abdomen. Numerous cases of hysteria, neurasthenia, and hopeless invalids have been restored to perfect health by proper exercise, belts, etc., and lastly by operation. The writer

emphasized a greater study of this most interesting condition. The symptoms in brief were: Emaciation, constitutional weakness, nervous irritability, pain in various regions, relieved by lying on back; pulsation of the abdominal aorta, vomiting, etc. The varieties were: Gastropsis, enteroptosis, coloptosis, mobile cecum, prolapse of spleen, kidney, or liver, varicocele, hemorrhoids, and numerous others, existing alone or in groups. In prolapse of stomach and bowel, considered in this paper, the x-ray has been of considerable aid. It has shown the classical anatomical location of the stomach to be erroneous. The etiological facts were bad habits of eating and drinking, exercise, improper clothing and footwear, infections of teeth, air passage, etc. These factors were taken up separately and discussed. These cases were always treated palliatively first and operation only as last resort. The use of proper fitting belts, the author's modification of Galland's binder, absolute rest with special diet, nurses, and elevation of bed often resulted in absolute cure. If all these measures failed operation was performed. The author was in favor of the Duret-Rovsing operation. The abdomen was opened from the ensiform to the umbilicus in the midline. If necessary, the liver and colon were fixed. The stomach was fixed by three large silk sutures passed out of the abdomen and tied over a glass plate.

Dr. CARL E. BLACK of Jacksonville, Ill., stated that thanks were due to Dr. Kreider for bringing this condition to our attention. The x-ray was of great help. The careful study of many cases of hysteria and neurasthenia placed these on a sound pathological basis. He stated it was difficult to diagnose the extent of ptosis at times.

Dr. ROBERT C. COFFEY of Portland, Ore., laid special stress upon making a proper diagnosis in reference to the organ or organs which were producing the symptoms, and if the patient had a retroverted uterus causing her symptoms not to perform a gastropexy and expect a cure.

Dr. KREIDER in closing laid special stress on x-ray examination and that the nervous conditions are caused by the ptosis and not the ptosis by the nervous conditions. Treatment of the ptosis cured the nervous diseases.

A New Principle in the Surgical Treatment of Brain Tumors.—Dr. ARTHUR C. STRACHAUER of Minneapolis stated that craniotomy for brain tumors, with or without focal symptoms, not infrequently failed to disclose the neoplasm, owing to its deep situation or variety as an infiltrating glioma or the position of the craniotomy. The decompression relieved certain symptoms, as severe headache and ocular symptoms, for the time being and then the individual case was left to die. In brief the writer urged a dual operation, combined with simplicity in technique and absence of all mechanically driven tools. He urged all the well known points in favor of preliminary decompression and concluded that there was a very bright outlook for the future of brain surgery.

Kondoleon's Operation.—Dr. WALTER E. SISTRUNK of Rochester, Minn., stated this operation was described by Kondoleon of Athens, Greece, in 1912 for elephantiasis, the object being to secure an anastomosis between the superficial and the deep lymphatics. Technique—two long parallel incisions on each side of the leg were made. The skin was removed; also the superficial fat at this stage undermining the skin edge. The aponeurosis was removed in a large separate layer and the incision was closed with silkworm gut sutures without drainage of the wound. Matas reported two cases in 1913 with good results. The elephantiasis usually followed infections or recurrent attacks of erysipelas. The author reported seven cases in all, three arm cases and four leg cases. All cases improved after operation. Two immediate results were obtained. From one case a streptococcus was isolated from a vein removed with fusion. The writer first followed Kondoleon's operation and later modified it by removing more skin. He stated few vessels required ligation. Patients were usually up in ten days. Sometimes the operation was performed in two sittings. A bandage for several months was applied, removed, and replaced if the swelling returned.

Dr. ROYSTER cited a case showing that the filaria is not a common cause of elephantiasis in this country. He

advised the reading of Dr. Matas' exhaustive article. In his own case of elephantiasis following a recurrent erysipelas in a colored man he operated on the patient with fair results. A subsequent operation was required.

Dr. GESSNER of New Orleans congratulated Dr. Sistrunk on his excellent results. He cited three cases of his own. All the cases were improved, but not one was cured.

Dr. SISTRUNK, in closing, answered the question that the internal saphenous vein was cut with impunity. He thanked the gentlemen for the discussion of the paper.

SECTION OF THE PRACTICE OF MEDICINE.

First Day—Wednesday, June 12.

DR. LAWRENCE LITCHFIELD OF PITTSBURGH IN THE CHAIR.

Dextrose Intravenously as a Therapeutic Agent.—Dr. LAWRENCE LITCHFIELD of Pittsburgh delivered the chairman's address on this subject. He said, in part, that the intravenous injection of dextrose was far reaching in its effect and life saving in results. It was used to overcome dehydration, intoxication, and nitrogen starvation. Dehydration was the most potent for evil. It might be caused by nausea, vomiting, diarrhea, sweating, hemorrhage, acidosis, inflammatory exudates, etc. The most characteristic picture of dehydration was seen in cases of Asiatic cholera, Shiga dysentery, and acidosis, characterized by small, thready pulse, rapid respirations, pinched face, sunken eyes, cold, clammy skin, restlessness, hallucinations, delirium, and coma. Following the intravenous injection of dextrose the picture changed; the pulse became fuller and stronger, face brighter, disinclination for taking water disappeared, the kidneys were stimulated, restlessness disappeared and the patients frequently went to sleep while receiving the injection. Results were due not to the water alone but to the stimulating action of dextrose upon the metabolism of the cells, which was seen by the fact that desperately sick patients, after a single injection of 400 to 500 c.c. of a solution of dextrose, frequently recovered without any further interference. If dehydration was marked extra water might be supplied by mouth or by the Murphy drip, but often it was necessary to repeat the injection after six, eight, or more hours. For over nine years Dr. Litchfield had been using a twenty-five per cent. isotonic solution of dextrose where salt solution had been previously used. He had used it in cases of pneumonia, purulent pericarditis, meningitis, alcoholic intoxication, and in surgical cases before operation, and after operation for vomiting and acidosis. The technique of administration was that of salvarsan injection. Occasionally sharp reactions, characterized by a chill and a rapid rise of temperature to 107° or more occurred, but the patients usually got better. It was possible to inject a large amount of the solution; as much as 1,700 c.c. had been given in 11 hours. The solution should not be injected rapidly; one hour for injecting 200 c.c. was a safe method.

Further Studies in the Treatment of Acute Poliomyelitis with Immune Horse Serum.—Dr. EDWARD C. ROSENOW of Rochester, Minn., presented this communication in which he said he had succeeded in isolating a streptococcus-like microorganism, which when injected into animals caused paralysis similar to that of poliomyelitis. That microorganism had strong anaerobic properties, resisted glycerization, and could be demonstrated and isolated from every case in which poliomyelitis virus had been used. The serum which he had obtained from horses, which had been immunized against that streptococcus-like microorganism had been found to possess high agglutinative powers for the poliomyelitis virus. The curative action of that serum had been first tried upon rabbits. Dr. Rosenow showed by means of lantern slides pictures of rabbits in which various degrees of paralysis had been produced by injection of the microorganism and in which the paralysis had disappeared rapidly after the injection of immunized horse serum. During the epidemic of poliomyelitis in Davenport, Iowa, he tried the efficacy of the serum upon humans. The results had been excellent. In all cases, with slight or no paralysis, re-

covery followed the injection of serum. Cases with very marked paralysis with evidence of respiratory involvement all showed marked improvement. Sixty cases in all of epidemic poliomyelitis were treated with the serum. He had also treated five sporadic cases, supposed to be the most fatal, with recovery in every case. He felt that the evidence of the efficacy of the serum was so strong, that the observations had not been faulty. He had seen nervous children go to sleep after an injection and patients almost at death's door had promptly recovered after an injection of serum. Since the serum was beneficial in sporadic cases he hoped that many physicians in private practice would give it a trial. There was a large supply of serum on hand and it would be sent free to any physician upon application. As to its harmlessness there could be no question.

Dr. ROY of Washington, D. C., asked Dr. Rosenow to explain what changes could have taken place in the nerve tissues where a paralysis had disappeared so quickly. He had observed that paralyzed pigeons promptly recovered from their paralysis upon the administration of a teaspoonful of brewer's yeast. Dr. Rosenow replied that there was evidence that the paralysis was a physiological one. In the beginning of a flaccid arm there was no destruction of motor cells, there was merely a cessation of physiological function. Much of the apparent paralysis was due to a cessation of physiological function and not to death of nerve cells. In rabbits death was due to cessation of physiological activities and not to death of nerve cells and an injection of a neutralizing serum produced a restoration of the function.

Pulmonary Compression Signs Associated with Fibrinous Pericarditis.—Dr. HENRY A. CHRISTIAN of Boston read this paper. He said that in cases where the heart showed physical signs of acute pericarditis, one very frequently found over the lower portion of the left back an area of dullness of varying size with bronchial breathing and bronchophony. Writers of text books and others had called attention to modified areas of dullness in the left lower back in the presence of pericarditis with effusion; they had all, however, emphasized the presence of large quantities of fluid in the pericardial sac. His experience had been different. Of fifty-seven cases of acute or fibrinous pericarditis he had studied thirty-nine, or seventy-three per cent., had shown pulmonary signs in the left lower back, but in none of the cases had there been any indications of the presence of extensive pericardial effusion; there might have been some fluid in the posterior portion of the sac but none in the anterior portion as the friction rub was heard all over that area. One of his patients, a woman forty-eight years of age, was admitted to the hospital with a history of rheumatism one week prior to her admission. Examination of her heart and lungs upon admission was negative. On the seventh day after her admission to the hospital she suffered from an attack of rheumatism; on the twelfth day a friction rub over the pericardium appeared; on the twenty-third day heart-block developed; several days later dullness and bronchial breathing appeared over the lower left back; and in about ten days the signs disappeared. During the development of the pericarditis and the appearance of the pulmonary signs the temperature had fluctuated between 100° and 101° and gradually returned to normal. In two patients who had died, autopsies showed an absence of fluid in the pericardial sac, and in one there had been a small amount of fluid present in the plural cavity with atelectasis of lung tissue of the left lower lobe. The pulmonary signs might be explained as due to consolidation of lung tissue or to fluid in the plural sac, the result of the extension of the inflammatory pericardial process to the pleura and lungs. He thought that the pulmonary signs had resulted from compression rather than from consolidation of lung tissue or fluid in the plural cavity. In his experience there had been no large amount of fluid observed in the pericardial sac and there had been no indication for tapping the pericardial cavity. The pulmonary signs had no relation to the condition of the patient, there had been no pain and the respiration had not been changed. Most patients recovered, but the pulmonary signs had no bearing on the prognosis. In some cases

the pulmonary signs had appeared before the pericardial friction rub.

Dr. ROBEY of Boston said the subject was a very important one, for the physical signs were to be misinterpreted. McKenzie had described a case of pericarditis in which he had tapped the pleural cavity, mistaking the signs in the left lower back for pleural effusion. The literature mentioned cases where in the presence of such pulmonary signs pericarditis had been suspected but aspiration of the pericardial sac had failed to bring fluid. In one case some pleural fluid had been removed, but the pain had persisted and two days later fluid was removed from the pericardial sac. When the heart was pushed forward by the fluid in the posterior portion of the sac the diagnosis might be very difficult as the heart sounds were so prominent that fluid was doubted. In such cases the x-ray revealed presence of fluid. Pericarditis, even of the purulent type, was seldom accompanied by pain; when present it was apt to occur early. He quoted Dr. Chapin who had said that he had practically never aspirated a pericardial sac. Whether the pulmonary signs observed in such cases were due to compression or extension of the inflammatory process to the lung was a hard question to answer.

Dr. POWER of San Francisco said that pulmonary signs similar to those described by Dr. Christian had been frequently observed by him in cases of chronic nephritis, and in one of his cases where the patient had died similar pulmonary signs had been observed three days prior to death. The autopsy in that case showed a small heart with very little fluid in the pericardial sac, but there were definite signs of pericarditis on the anterior surface of the sac; the lungs showed no consolidation at all, but some slight congestion. In that case the pulmonary signs could not have been due to compression or extension of fluid as the heart had not been enlarged.

Dr. WYNN of Indianapolis said that the explanation of the presence of the pulmonary signs observed in pericarditis would depend on our conception of the *modus operandi* of rheumatism. When there was a history of rheumatism followed by the appearance of a friction rub over the pericardium it was usually thought that infection had started in the tonsils and from there through the blood stream affected the heart. It was his opinion that many cases of pericarditis had resulted from contiguity of inflamed pulmonary tissue. He thought the subject was a very timely one. In many cases autopsies frequently showed white spots over the pericardium which were suggestive of a previous pericarditis but which had not been diagnosed during the life of the patients. He thought many cases of pericarditis remained undiagnosed. He thought that pericarditis often arose by contiguity of pulmonary tissue in a bronchopneumonia and that it was possible that in some of the cases mentioned by Dr. Christian the pericarditis had been due to some pulmonary trouble and not that the pulmonary signs were due to the pericarditis.

Dr. HEAD of Minneapolis said that the difficulties of actually determining from physical signs whether fluid was present in the pleural or pericardial cavities were baffling to the best of men. Where there was a dry tap with a moderate enlargement of cardiac dullness the fluid might be in the posterior position. He wished to know whether in the case of Dr. Christian's patient, where an autopsy had been performed, there had been found in the posterior portion of the pericardial sac a quantity of a heavy fibrinous exudate.

Dr. LITCHFIELD of Pittsburgh, chairman, said the subject was very timely. More would be learned about such conditions in the next few years. Experience in army camps had shown many cases of pericarditis to have been due to a streptococcal infection. In cases that were tapped it was often difficult to state where the fluid came from. The fluid might be pocketed in every conceivable form, making it very difficult to be certain as to its source. He thought he knew where fluid came from until in his last case he had tapped over the pericardium and had obtained pleural fluid. As a diagnostic aid for such cases repeated fluoroscopic examinations by one experienced in that work were most invaluable. In his experience that was the most important method of diagnosing the presence of fluid.

Dr. RYAN of Des Moines said he wished to emphasize the point mentioned by the chairman regarding fluoroscopic examinations. In camp Dodge excellent results had been obtained by fluoroscopic examination. In a number of cases with a beginning pericarditis following rheumatism signs of hypostatic congestion of the left lower lobe had been present. By placing the patient in an upright position and examining him with a fluoroscopic a shadow could be seen. By expectant treatment all physical signs disappeared. In many cases the physical signs had followed a streptococcic infection of the throat. Those infections were often neglected. If timely treatment were given for throat infections many cases of pericarditis and pneumonia would disappear. Some cases of hypostatic congestion often cleared up under ordinary antiseptic treatment of the throat.

Dr. CHRISTIAN in closing said he wished to emphasize that the prognosis in those cases was good. From the physical signs observed in those cases one was apt to consider them serious; pneumonia was often suspected; they all got well and without tapping. In his experience x-ray did not give much information in such cases. Frequently cases were definitely diagnosed by the x-ray as pericardial effusions, but no fluid had been found. Fluid in the pericardial sac sufficient to embarrass respiration was rare. He had had two cases of pericardial effusion. In one he had removed by tapping 400 c.c. of fluid and in the other 600 c.c. In the second case the patient died and a chronic fibrinous pericarditis had been found upon autopsy. Neither of those cases with rather large amounts of fluid had shown the pulmonary signs he had described. He did not think there were many indications for tapping of the pericardial sac. He was by no means sure as to the cause of the pulmonary signs he had observed in his cases, but he was inclined to attribute them to compression rather than to consolidation of lung tissue or fluid in the pleural cavity.

Ulceration of the Soft Palate Resembling Syphilitic Perforating Ulcer Due to Fusiform Bacilli and Spirilla (Vincent's Angina).—Dr. SYDNEY R. MILLER of Baltimore read this paper in which he reported the case of a man forty-five years of age who had been suffering with a circumscribed ulcer of the soft palate; the ulcer had a punched out appearance with undermined edges and was on the point of perforation. The patient had noticed three days previously some soreness in the mouth which had spread and had rapidly become worse. The case had been thought to be specific and the throat examiner made a diagnosis of gumma of the palate. As the patient had stoutly denied specific infection and the Wassermann reaction with the blood serum was negative, a smear was made, which under the dark stage had shown the presence of fusiform bacilli and spirochetes; the latter, however, did not, either by their morphology or motility, resemble the *Spirocheta pallida*. A diagnosis of Vincent's angina was made and under local antiseptic treatment a rapid cure had resulted. Dr. Miller thought the importance of Vincent's angina was not being sufficiently recognized. Among the British and French troops sporadic cases of stomatitis caused a great deal of invalidism, and 23 per cent. of all the mouth and throat affections were due to spirochetes and fusiform bacilli. The disease was supposed to have been infectious, and there were also supposed to have been carriers. There were two types of lesions, the *superficial*, presenting the appearance of a diphtheroid membrane, which was friable, and upon removing came off easily, leaving a bleeding surface, and the *ulcerative* type, which was usually located on one tonsil and presented the appearance of a creamy pulaceous surface, leaving upon removal a bleeding area. The parts most frequently involved were the gums, the tonsils, and the buccal mucous membrane. It would be best, Dr. Miller thought, to limit the name of Vincent's angina to lesions of the tonsil alone and to apply the name of Vincent's disease to other lesions. The striking point in connection with Vincent's angina was the lack of constitutional symptoms in proportion to the appearance of the lesion. In the French army, however, the men had seemed to suffer from depression of spirit; they were sulky, irritable, and seemed to have lost their "pep." Predisposing causes were not known, though tobacco and lack of oral sepsis might be con-

sidered predisposing causes. It had been proven that the affection was definitely contagious and was being transmitted through the use of the tooth brush, pipe, etc. As to the exciting cause, there were still differences of opinion; some did not accept the fusiform bacilli and the spirochetes as the exciting cause. In the early lesions fusiform bacilli predominated, but in the later ulcerative stages the spirochetes were more frequent. Some considered the bacilli and the spirochetes one and the same organism, but he did not think so, for the theory of pleomorphism had been long ago exploded. The condition must be differentiated from acute tonsillitis, diphtheria, and luetic infection. Acute tonsillitis showed more severe constitutional symptoms. Diphtheria could be diagnosed by bacteriological examination of cultures, and luetic infection by the Wassermann reaction.

Dr. MARSHALL of Camp Grant said that he had seen a good many cases similar to those described by Dr. Miller while he had been with the British forces. Bowman of Toronto frequently found in such cases *Ameba buccalis* associated with spirochetes. In forty cases observed by himself he had used a mixture of wine of ipecac, for its action upon the ameba, potassium arsenite, and glycerin to sweeten the mixture; all the cases had cleared up quickly under that treatment.

Dr. SLADEN of Detroit said that there were three reasons for non-recognition of cases of Vincent's angina. One was due to the intimacy of the doctor and the dentist; the latter considered mouth infections his domain; the second reason was that most of the cases responded promptly to ordinary household throat remedies, and the third reason was the similarity of the lesions of Vincent's angina with the punched out syphilitic ulcer. In many cases where no syphilis was present the lesions had responded to arsenical preparations. Fatalities were met with occasionally. He had observed one case in which the patient had died; the larynx was involved and bronchopneumonia was also present. Injection of salvarsan had been tried without any relief.

Dr. CHRISTIAN of Boston said there were two points of interest in the study of the cases presented, the similarity to a syphilitic lesion, and the question whether the organisms described were the cause of the infection. There were many cases of perforating ulcers which were considered as due to an old syphilitic infection and where the Wassermann reaction was negative. Many perforating ulcers of the nasal system might not be syphilitic. As to the exciting cause he thought the fusiform bacilli and spirochetes which had been mentioned were too often and too easily found. They had been seen in ulcerative conditions anywhere in the body; they had been found in stomatitis which had followed the administration of mercury, in cases of noma following measles, and in ulcer associated with chronic nephritis. There was considerable reason for doubting that the organisms were the cause of the conditions described. They were useful, however, for diagnostic purposes.

Dr. MILLER, in closing the discussion, said he hoped he had not left the impression that the situation was very clear. The specificity of the organisms was still questionable. They were found in healthy conditions, but possibly the tissue had to be damaged before the organisms could produce their deleterious effect. The fact that they had been found in mercurial stomatitis showed that apparently mercury had a strong relation to that disease. In the French army many cases in which salvarsan had been administered had developed Vincent's angina.

The Early Diagnosis and Intravenous Treatment of Epidemic Cerebrospinal Meningitis.—Dr. WILLIAM H. HERRICK of New York presented this communication, in which he said that as a result of a study of 250 cases of cerebrospinal meningitis which had occurred in Camp Jackson he had come to the conclusion that the disease was primarily a general sepsis and that the meninges were secondarily involved. As a result of that conception of the disease diagnosis had been made early and the treatment was given to combat a general infection and not a local one. They had studied a large number of cases with all sorts of suspicious symptoms, and as a result they had learned to recognize the disease in the premeningitic stage, which was character-

ized by general systemic symptoms, and which lasted from a few hours to a few days. In 40 per cent. of the cases a diagnosis had been made in the premeningitic stage. The symptoms during that stage of the disease were a temperature rarely above 102°, slow pulse, with vagal irritability; the manner and facial expression of the patients were characteristic; they were dull, apathetic, resented interference; they used the least possible amount of effort to answer questions, the voice was low, and they quickly lapsed back into quietness; the face, and especially the ears, showed cyanosis; the secretions were viscid; the tongue, when protruded, was covered with sticky saliva; the upper respiratory tract was frequently involved; a petechial rash usually appeared very suddenly. In milder cases there was a papular rash like that of chickenpox; there was a lack of balance of the deep reflexes, one side showing an exaggeration, while the other showed a normal, diminished, or absent reflex. A lumbar puncture when any of the above symptoms were present usually revealed a clear fluid containing meningococci. If the spinal fluid from the first puncture failed to reveal the presence of meningococci another puncture was made two hours later, when meningococci were found to be present. The failure to find the germs in the fluid obtained from the first puncture was due to the fact that the germs were frequently confined to the upper spinal spaces. Once the diagnosis was made, the treatment aimed to sterilize the blood stream and rid the system of the meningococci. The treatment consisted in an intraspinal injection of 1 c.c. of antimeningococcic serum, for the purposes of desensitization, which was followed one hour later by the intravenous injection of a 100 to 130 c.c. of antimeningococcic serum. It was very important to inject the serum slowly at the rate of 1 c.c. per minute during the first 15 minutes and stop the injection at once if any untoward effects appeared. The injection was repeated in 8 to 12 hours in severe cases and in 24 hours in milder ones. The average case received four to six intravenous injections, getting on an average about 400 c.c. of serum. In addition the patient was receiving repeated intraspinal injections of 20 c.c. of serum, the spinal canal being drained before the intraspinal injection. As a result of that form of treatment the course of the disease was shortened, complications were less frequent and less severe, and the mortality was reduced from 40 per cent. with the old form of treatment to 14 per cent. with the new one.

Dr. GUTHRIE of the Army said the Section was very fortunate in receiving such an early report from Dr. Herrick. He wanted to know the type of serum Dr. Herrick had used and the maximum dose he had given to any one patient. The general conclusions of Dr. Herrick were correct with a few reservations. Out of 138 cases he had seen in Camp Beauregard, Louisiana, the picture during the premeningitic stage was that of respiratory disease, so that from the first they called that stage meningitis-grippe. In his experience the most frequent mistake in diagnosis was to call meningitis pneumonia. He could not agree with Dr. Herrick that the occurrence of the rash marked the case as a severe one; in his experience cases with extensive rashes yielded to treatment. He wished to emphasize the possibility of reinfection; the spinal fluid was able to harbor the meningococci for a long time. In some cases the clinical picture of the disease suggested yellow fever; the black vomit of yellow fever had been very strikingly reproduced in some of his cases, and the pathological findings upon autopsy had also frequently suggested yellow fever. He felt humiliated to confess that in his camp the mortality with the same method of treatment as outlined by Dr. Herrick had been about 50 per cent., and that was why he wished to know the type of serum Dr. Herrick had used. In his own camp they had been compelled to use a serum which the manufacturer had admitted was not ripe. He agreed as to the efficacy of the intravenous serum treatment.

Dr. SCHENCK of Norfolk wished to know about Dr. Herrick's experience with carriers of the disease. In a naval base in his vicinity there had been a number of meningitis cases, and later on 32 cases developed among the civil population. As six cases had resulted fatally, they had taken special precautions regarding carriers. In the 32 cases they had traced 400 contacts,

but none of these had developed the disease, while the 32 cases had given a history of 90 contacts with the naval base, and it had been thought that the disease had spread from the naval base to the civil population. At the naval base they had been at first very careful in weeding out the carrier, but later on they had abandoned that plan.

Colonel RUSSELL of the Army said that the question of carriers was a very complicated one. There had been no definite opinion reached. The difficulty was to know which carrier was negligent; some carriers carried pure cultures all the time, while others carried them only occasionally. If it was possible to take care of the chronic carrier, much would be done. In camps where "carrier" work had been done early and carefully the epidemic was controlled quickly; in other camps where this had not been done the epidemic had persisted longer. There was an interesting hypothesis regarding the infectiousness of meningitis, namely, that the disease was easily transmitted, but most people did not acquire meningitis because they had an immunity against it.

Dr. HAMBURGER of Chicago wanted to know whether in Dr. Herrick's series all the cases had been the result of general primary infection. In a number of cases he had observed no meningococci had been found in blood cultures. In 40 cases treated by the old method the mortality had been 16 per cent.

Dr. HERRICK, in closing the discussion, said he had not made up his mind about carriers. He believed every case of meningitis was a systemic infection as every case of pneumonia was a general pneumococcic infection. As to the type of serum, they had first used a commercial product, but had not gotten such good results, so they had used sera prepared by the Rockefeller Institute, the New York City and New York State laboratories. If a case did not respond to one type of serum they had tried another type. The maximum amount of serum given one patient had been 150 c.c. for 10 doses. Preliminary respiratory symptoms were quite frequent. The similarity between pneumonia and meningitis was so striking that when the first cases had been observed the physicians in camp had thought they had discovered something new, but Osler and others had described that similarity. In cases of reinfection it was necessary to repeat the entire cycle of treatment. He had not observed any hemorrhagic vomiting in meningitis cases. Hemorrhages into the meninges had not occurred in many cases. In only one case an autopsy had shown a hemorrhage into the meninges.

The Training of the Medical Officers in the Army.—Dr. WILLIAM N. BISPHAM of Fort Riley, Kan., presented this paper. At the outbreak of the war, he stated, three officers' training camps were established, Camp Harrison, Fort Riley, and Fort Oglethorpe; Camp Harrison was soon abandoned. From the inception of the camp idea we went on the principle of making the medical officer a 100 per cent. military man, after which he could utilize his medical knowledge to better advantage. The actual treatment of the sick was by far the least of the medical work; prevention of disease and keeping the enlisted men in good health was far more important. Although military medicine had not been neglected, the keynote of instruction was discipline. Another point emphasized was physical development, with great benefit to the many civil practitioners who had not had time to cultivate this feature. On account of the medical officer's close association with the enlisted men in his duties he was given the same training as the enlisted man, and in some instances prominent physicians were disciplined for violations of military law. After a short time medical instruction was instituted and the courses now being given were second to none. Preventive medicine, divided into sanitation and epidemiology, received most attention. The instruction was practical rather than didactic; officers were given camps to inspect and their reports were checked up. Epidemiology appeared to be little known by the civil practitioner and careful instruction was given in it. Some physicians did not take kindly to the train-camp idea at first, but those who went through the course testified to its value and the *esprit de corps* developed.

(To be continued.)

Miscellany.

Evolution of Hygiene in Argentina.—This subject is partially covered by Coni in a series of articles which appear in the *Revista de la Asociacion Medica*. In the January-February number the animal industry is discussed from the standpoint of hygiene. Meat inspection goes back to 1881 in which year the municipal veterinary chief in Buenos Aires inaugurated the practice at the public slaughter house in association with the head executive of the latter. The printed regulations comprised twenty-three provisions. Gradually the number of official veterinaries was increased while in 1887 a service of slaughter houses and butchers was organized as part of the municipal chemical office. In 1892 the meat inspectors became part of the department of technical hygiene.

In 1894 it was realized that no official provision was in existence for dealing with epizootics. The first real move in this direction was a small bacteriological laboratory established under the auspices of the Argentine Rural Society, which became the nucleus of a veterinary sanitary police control, in which all contagious diseases were reported and a record made of the morbidity, mortality, etc. Quarterly reports were published.

In the course of time the animal industry became an integral part of the agricultural department, while the agricultural and veterinary school became a part of the national university.

In 1881 the medicohygienic inspection of school children began in Buenos Aires. At that period the movement was already active in Brussels, Boston, and a few other cities. Since this form of preventive medicine began in Brussels, in 1875, Argentina was early in the field. In addition to medical inspection in the narrower sense the subjects of light, heat, ventilation, furniture, latrines, etc., were covered. Gymnastics were introduced and attention given to anthropometry. Schools with running water were provided with shower baths. Errors of refraction were corrected and carious teeth filled. Vaccination and revaccination were practised in the school buildings. The administration of school hygiene seems to have been patterned largely on that of Brussels. The results obtained in the schools first tested led to the generalization of the movement in Argentina. Colonies for weak children were first established in 1902.

The Interallied Scientific Food Commission.—The first meeting of the Interallied Food Commission, formed in November last, according to *Science*, May 10, 1918, was held in Paris on March 25, and the following days. At their first sitting the commission was received by M. Victor Boret, minister of agriculture and food. In his opening address M. Boret pointed out that the object of the conference was to study the best means of utilizing the very small food resources at the disposal of the allies, having proper regard to the facts of physiology and political economy. He sketched shortly the work of the commission and his suggestions were embodied later in a series of questions which were adopted by the commission as the problems which would immediately occupy its attention. The commission agreed to

establish a permanent central secretariat in Paris, M. Alquier being appointed secretary. In addition to the central secretariat it was agreed that a secretary to the commission should be appointed in each of the allied countries. At its meetings, which lasted till March 29, the commission considered many important questions relating to the minimum food requirements of man, and to the production and distribution of food supplies. The commission will reassemble at intervals, in Paris, or in one other of the allied capitals.

The Birthrate and Infant Mortality.—Dr. Eric Pritchard, writing in the *Eugenic Review*, November, 1917, says that so far as numbers of population are concerned, a high birthrate is infinitely more important than a low deathrate among infants, as Dr. W. G. Hope very clearly proved in his report to the Carnegie Trust, 1917. To quote Dr. Hope's own words: "Take a town with a population of 750,000 having a birthrate of thirty persons per thousand and an infant mortality of 120 per 1,000 births; if the birthrate falls 3.6 per 1,000, namely to 26.4, and every infant lives, not one death taking place under twelve months of age, an impossible eventuality, the increase in the population is precisely the same as it was when the higher birth rate prevailed with the high infant mortality rate of 120 per 1,000. Following this line of argument, it suggests itself that if, in the national interest, our object is to maintain the population without consideration of quality, it would be more logical to encourage such conditions as obtain in Sunderland and Middlesborough, where the birth rates are respectively 30.2 and 28.5 and the death rates 151 and 152, than to multiply garden suburbs where the birthrates are correspondingly low and the death rates negligible. Although it does not necessarily follow that the quality of the national stock will deteriorate from the preponderating increase of the physically defective elements of society to which modern industrial conditions in Great Britain dispose, it is highly probable that the national interests will suffer by such a proceeding, although we are not in a position to say exactly what physical or mental type will fit in with future developments. For his part, Pritchard would rather put his faith in those stocks or in those families which have proved their superiority throughout the centuries than in those which have proved their inferiority by remaining permanently submerged and who are content to live in crowded unsanitary areas. If this is wrong, he says, little faith can be reposed in the principles of eugenics and heredity is a fraud. Pritchard concludes that, speaking generally, one may say that the great war has stimulated human endeavor to find a satisfactory solution to the problems of infant mortality and of the falling birthrate, and has materially modified public views with regard to the true significance of these important factors in the national life.

Although economics, housing, and industrial considerations greatly influence both the birthrate and deathrate, there can be no question that so far as the deathrate is concerned the most important factor is the intelligent application of the known principles of hygiene and mothercraft to the problem of rearing children.

 Obliteration of the superior vena cava,
 four cases of, 1140.

- Observations on gall-bladder disease and its surgical treatment, 147; on the treatment of diabetes insipidus with Infundin, 127.
- Obstetrics, difficulty caused in by angioma of liver, 40; Prochownik's diet in, 741; tyramine in labor in, 40.
- Occupation and mortality, 1046.
- Occupational diseases, physicians requested to report, 201; therapy for women, course in, 462.
- Ocular lesions, on, from air compression resulting from exploding shell, 563; palsies of apoplectic nature during an attack of severe coughing, 616; wounds from mine explosion, 564.
- Oculist, how should the, proceed in hopeless cases, 1140.
- Oleomargarine, bill removing restrictions on, 645.
- Omnibus treatment of stomach affections, 33.
- Operation, drafted men must submit to, 111.
- Ophthalmia, military, in the Austro-Hungarian army, 564.
- Ophthalmoplegia, a case of bilateral total, 724.
- Oplum alkaloids, the relation of the chemical structure of, to their action on smooth muscle, and the pharmacological and therapeutic properties of some benzyl esters, 1005.
- Optometry, right to practise, 594.
- Orbit, carcinoma of, result of operation of, 303.
- Organism, human, influence of balancing movements on the, 121.
- Organo-therapy, menstrual epistaxis and, 208; menstrual epistaxis and its treatment by, 253.
- Oriental front, surgical observations on the, 697; diseases in the British Isles, 1135.
- Orthodontia in respiratory obstructions, 598.
- Orthopedic principles in general medicine, 711.
- Orthostatic purpura, 962.
- Osteo-arthropathy, hypertrophic, of pulmonary origin, 346.
- Osteomalacia following recurring puerperal anemia, 297.
- Osteopaths, bill to remove restrictions from, 645.
- Osteopathy, scope of license to practise, 194.
- Othematoma in prisoners, 827.
- Otology and the war, 154.
- Otosclerosis, 251.
- Owen bill, 288, 289; resolutions supporting the, 788.
- Owen-Dyer bills, the, 509.
- Ovaries, fibrous cysts of the, 431.
- Ozena, alleged curability of, 377.
- Ozonized chlorinated oil of eucalyptus, a preliminary report of the use of, 806.
- P
- Pacini, August J. P., stammering, 800.
- Paget, O., the diagnosis and treatment of obscure cases of tuberculosis, 144.
- Paget's disease, 351.
- Pain, abdominal, in children, surgical significance of the, 96; acute abdominal, hydronephrosis as an underlying cause in attacks of, 870.
- Palms, pink, in influenzal pneumonia, 162.
- Pancreatic organotherapy, colic reaction and, 255.
- Pancreatitis, subacute, treatment of certain forms of, 213; ultimate results of chronic and subacute, 1144.
- Paralytic, encouraging the, to recover, 424.
- Paralysis, facial, surgical treatment of, 121; functional, from disuse, 786; left-sided, of the extraocular and intraocular muscles with atrophy of the left optic nerve, 616; of peroneal nerve, spring plaster casts for preventing deformities due to, 121; of the seventh pair, the sympathetic nasofacial reflex in, 520; progressive, and malignancy of the hypophysis, 432.
- Paratyphoid, vascular affections in, 913.
- Paratyphoid B. fever, prognosis of, 345.
- Parent complex, some manifestations of the, 664.
- Paris, the university union in, 909.
- Park, F. E., radium emanation in hay-fever, 284.
- Parkinson's disease and its treatment with parathyroid gland, some fragmentary notes on, 365.
- Patent urachus, with abscess, complicating an hypertrophied prostate, a case of, 491.
- Pathogenic microorganism, specific for every, 212.
- Pathology, liver, function of, in, 82; renal, diagnosis in, 519; without infection, 553.
- Patients with incurable diseases, registration of, no longer demanded, 163.
- Paulsen, A. E., and Schlapp, M. G., report on 10,000 cases from the Clearing House for Mental Defectives, 269.
- Pediatrics, internal secretions and, 150.
- Pellagra, masked, 363; public health service combating, 866.
- Pelouze, P. S., chronic urethral discharge, 546.
- Pelvic abscess, rectal surgery for, 1113; bloodvessels, stereoscopic radiographs of the, 615; operations, enterostomy and enterocolostomy in the treatment of intestinal obstruction following, 1108.
- Pelvis, angioma of liver reaching into, and causing obstetric difficulty, 40; contracted, extraperitoneal cesarean section for, 524; female, pus in the, 1113.
- Pemphigus bulla, the pathogenesis of the, 827, 913, 1057.
- Pencil, explosive, the, 27.
- Penetrating missiles, the tenor of infectious bacteria on, 962.
- Perception efficiency of recruits, tests for, 285.
- Percival, J. B., primitive treatment of disease, 330.
- Perfrigerations and congelations, 599.
- Pericarditis, fibrinous, pulmonary compression signs associated with, 1147.
- Peritonitis, tuberculous, 304; tuberculous, secondary, 1110; ulcer, therapy of, 785.
- Phagocytosis, experimental researches in, 786.
- Pharynx, the treatment of malignant neoplasms of the, and nasal fossæ with radium, 697.
- Philadelphia School of Neurological Surgery, 373.
- Phillips, Sir John, 692.
- Phimosis, association of adenoid vegetations with, 377.
- Phosphorus, the effect of, on growing normal and diseased bones, 1099.
- Physician and psychology, 1054.
- Physicians, dispensary, wanted, 779; Motor Club of Philadelphia, 339; of the Napoleonic era, a brief biographical sketch of four, 969.
- Phthisis, iodine in treatment of, See Tuberculosis.
- Physiology, descriptive human, 731; of aerophagia, 100, 129; of "functional paralysis" of "voluntary" movement, on the, with a description of a case of inversion of the kinesthetic sensations, ???
- Pica, report of a case of, with unique complications, 922.
- Pigmentation, uses and causes of, 199.
- Pituitary solution, the use and abuse of, 1112.
- Pituitary therapy, diabetes insipidus and, 310.
- Pityriasis rubra (hebra), 1003.
- Plans, new, for health centers, 124.
- Plaster casts, spring, for preventing deformities due to paralysis of the peroneal nerve, 122.
- Pleural cavity, the removal of foreign bodies from the, 1057.
- Pneumocardium, artificial, case of, 38.
- Pneumococcus carriers, disinfection of, 119.
- Pneumonia, acute, immunization against, 877; acute dilatation of the stomach in, 388; acute lobar, 429; at Camp Upton, classification and results of treatment of, 475; at Camp Upton, classification and serum treatment of, 947; bacteriological study of postoperative, 876; bacteriology and serology of, 742; cases, nursing service cases for record number of, 818; chronic, report of a case, 590; common colds and, 114; face mask, value of, in prevention of, 165; influenzal, pink palms in, 162; lobar, rapid and simple method for the determination of type of pneumococcus in sputum of, 877; lobar, treatment of, 222, 248; plague menaces North China, 378; practical points in treatment of, 30; symptomatology and diagnosis, 742; treatment of twenty cases of group I lobar, with serum, 790.
- Pneumonias, treatment of the, 743.
- Pneumonic lungs, studies on the toxicity of, 878.
- Pneumococcus infections, the chemotherapy of experimental, 878; serum, production of, and the corresponding curves obtained by protection and agglutination tests, 877.
- Pneumothorax, the prognosis and treatment of, 873.
- Poet's committee reaches goal, 71.
- Points, practical, in treatment of pneumonia, 30.
- Poison, an arrow, used by a low type of Brazilian Indian, 528; in cosmetics, 261.
- Poisoning, first symptoms of, by new "mustard" gas, 21; phosgene, 550; the principle of treatment in mercuric chloride, an experimental study, 606; trinitrotoluene, 72.
- Poliomyelitis, acute, complement fixation test with a specific antigen in, 922; acute, further studies in the treatment of, with immune horse serum, 1146; bacteriology of, 600; clinic for after-care of, 161; early history of, 967; experimental, active immunity in, 832; experiments on the production of antipoliomyelitis serum in rabbits, 831; macroscopic and microscopic findings in, 719; rat and, a theory, 1067; treatment of by chlorine water, 176; winter epidemic of, 26.
- Pollinosis, experimental, in guinea-pigs, 834.
- Polycythemia with focal symptoms, case of, 39.
- Polyglobuly, case of, with diminished globular resistance, 608.
- Polyserositis, 291; a case of, 791.
- Post-graduate medical school in France, 1066.
- Post-operative psychoses, 1103; retroflexion following operations for pus tubes, prevention of, résumé of cases, 522; thrombosis and embolism, suggestions for the prevention of, 650; treatment, 608, 697.
- Potter, N. B., streptococcus oral sepsis, 135.
- "Practising medicine"—removing superfluous hair, 682; without license, 68.
- Practitioner, general, a study of history and symptoms rather than physical and laboratory findings in diagnosis of pulmonary tuberculosis, as being of more value to the, 101; is the, responsible for articles left in his waiting room? 114.
- Precipitate labor and the war, 652.
- Pregnancy and heart failure, 296; and pulmonary tuberculosis, 343; double simultaneous extrauterine, 777; extending the care of, 1117; goiter in, 1110; hydrosalpinx with twisted pedicle simulating ectopic, 702; laparotomy during, 826; paritis following induced abortion in a case of pernicious vomiting in, 1114; strangulated ovarian cyst complicating, 526; sepsis, 874; twin, one child a monster, 40.
- Prenatal work, instruction and supervision of expectant mothers in New York City, 165, 205.
- Preparation, our, for the x-ray work of the war, 87; to care for war cripples, 70.
- Prevention of communicable diseases in modern warfare, 174.
- Preventive medical work in the dispensary clinic, opportunities for, 853.
- Problems, medical, on the Italian front, 69.
- Program, military antituberculosis, 156.
- Prohibition bill before New York State, 161.
- Projectiles as cause of wounds in head, necessity for surgical interference, 21.
- Prostatic cases, vaccine therapy in, 251.
- Prosthesis functioning at the will of the patient, the question of, 473; in lower jaw resection, 785; muscular plastic operations in amputation stumps from viewpoint of, 298.
- Protein bodies, intraglutinal injections of, influence of, on evolution of acute middle ear disease, 82.
- Pruritus ani, true, its association with pyorrhea alveolaris, 945.
- Prussia, illegitimacy in, 29.
- Psychasthenia, neurasthenia and, following shell shock, treatment of, 32.
- Psychiatry, classifying mania in, 244; differential diagnosis in, a comparison of methods in various disease states, 1000; normal and abnormal, 1123.

Psychopathology, 6; of selections of vocations, 318.

Psychoses and war neuroses, in France, care of, 22; manic-depressive, medicolegal aspects of, 336; post-eclamptic, prognosis of, 25; post-operative, 1103.

Psychotherapy, King's Evil and its relation to, 350.

Public health and internationalism, 566; law, new, 820; problems, government urged to take up, 906; regulations, infantile paralysis, 194; service remedies physical defects, 23.

Puerperal anemia, recurring, followed by osteomalacia considered as endocrine disturbances, 297; sepsis due to *Bacillus aerogenes capsulatus*, 744.

Puerperium, pleurisy during the, 430; pelvic floor repair during the, 745.

Pulmonary apices, percussion of, 254; compression signs associated with fibrinous pericarditis, 1147; resection, 1140.

Purpura hemorrhagica and acute articular rheumatism, the visceral lesions of, 1033.

Pseudohermaphrodite, male type, 522.

Pseudotabes, peripheral radicular, of traumatic origin, 874.

Pyelitis infantum, 519, 652.

Pyelitis, observations on, 448.

Pyelography and pyeloscopy in differential diagnosis of renal conditions, with reference to calculi, 88.

Pyeloscopy and pyelography in differential diagnosis of renal conditions, with special reference to calculi, 88.

Pyloric stenosis, congenital, 303; congenital, clinical, and experimental studies of, 305; congenital, roentgenological diagnosis of, 304.

Q

Quinine adrenalin hypodermoclysis in treatment of malaria, 112; and Warburg's tincture in malaria, 996, 1049; in human organism, 345; proper form of, for children, 1134; prophylactic use of, in malaria, with special reference to experiences in Macedonia, 1101.

R

Rabelais, teeth according to, 323.

Rabies in France, recrudescence of, 337; increase in Paris, 203.

Rabinowitsch, H., quinine and Warburg's tincture in malaria, 996; treatment of lobar pneumonia, 248.

Rachitis tarda, calcium and phosphoric acid metabolism in a case of, 122.

Radioactivity in therapeutics, 142.

Radioscopic, Grabsberg's, operative technique, 473.

Radiotherapy and myomectomy, the comparative value of, 651; and operative treatment of uterine myomata, comparative value of, 254; the cure of trigeminal neuralgia with, 563; rationale of, in uterine hemorrhage, 40; the value of, in myomata and metrorrhagia, 563.

Radium and roentgen ray in treatment of internal disease, value of, 87; emanation in hay-fever, 284; institute, the, 907; treatment of scars with clinical notes on military orthopedic cases, 738.

Rat-bite fever in the trenches, 69.

Rationale of radiotherapy in uterine hemorrhage, 40.

Rationing of London, 559.

Rations, invalids and compulsory, 647.

Reaction, Weil-Felix, etiology of, 345; Weil-Felix, significance of in diagnosis of typhus fever, 82; of immunity, produced by the Weil-Felix bacillus and their etiological significance in typhus fever, 168.

Reckford, F. F. D., food; classification of foods, preparation of foods, general consideration of dietetics, 229.

Reconstruction and rehabilitation problems as demonstrated by experience in foreign countries, 1127; acute surgery as related to, 1127; of Canadian crippled soldiers and the results, 1128; physical, 699; work, hospitals chosen for, 597.

Recruiting of the Medical Reserve officer, 348.

Recruits, perception efficiency of, tests for, 285.

Rectum, bleeding from, diagnostic significance of, 63.

Recurrent fever, bilious typhoid and Weil's disease, 35.

Red Cross, American, brief outline of personal observations in Italy and at the western battle front with the, 947; bureau of refugees and relief, 560; American, child welfare work in France by the, 567; American, meets emergency, 640; American, to care for prisoners, 559; American, to help in Switzerland, 950; and animal research work, the; a protest by the Buffalo Academy of Medicine, 866; British, 998; Christian scientists are not antagonistic to, 117; cooperation between army officers and, 374; expenditures, 110; farm in France, 374; feeding the school children in Paris, 1097; institute for crippled and disabled men, 78; makes record, 901; on transports, 508; relief work; French and American methods; construction and reconstruction work, 204; rescue aviators, 692; school for cripples, 156 stands by Belgium, 1051; traveling laboratories, 508; work of the, in Belgium and France, 736; working in France, 163.

Reeducation clinic, new, 640; of the deaf and speech defective, 1128; of the war blinded, 1128; vocational, of the war cripple, 655.

Reese, F. D., uterine fibroid tumors, 279.

Registration of patients with incurable diseases no longer demanded, 163.

Rehabilitation of the disabled soldier, 1127; reconstruction and problems as demonstrated by experience in foreign countries, 1127; results of, in foreign countries, 1129.

Renal eliminations, 80; gland, the functional exploration of the, in disease, 696.

Report, annual, of the surgeon general of the U. S. Public Health Service, 158; preliminary; immoral woman as seen in court, 73.

Rest and convalescent centers, saving those who cannot save themselves, 869.

Restoration, motor function of, in resected nerve, by end-to-end anastomosis, 11.

Revival of the cuirass in the present war, 176.

Rheumatism, articular, is trench-shin an? 154; acute articular, the abortive treatment of, 473; acute articular, the visceral lesions of purpura hemorrhagica and, 1033.

Richardson, Anna Mann, opportunities for preventive medical work in the dispensary clinic, 853.

Robbins, F., the physician before the law in some European countries, 592.

Robinson, Beverley, exaggerated views about the contagion and outcome of pulmonary tuberculosis, 238; practical points in the treatment of pneumonia, 30; quinine and Warburg's tincture in malaria, 1049; timely remarks about the treatment of malaria, 852.

Robinson, Edward Percv, a plea for the use of potassium nitrate in the treatment of cancer, 764.

Robinson, William J., the proper form of quinine for children, 1134.

Rockefeller fund, appropriations from, 201.

Rocky Mountain spotted fever, the etiology and pathology of, 1010.

Roentgen ray and radium in treatment of epithelioma, showing end results, 88; and radium in treatment of internal disease, value of, 87; diagnosis of abdominal diseases, 86; in diagnosis of diseases of thoracic cavity, 86; in internal medicine, symposium on the, roentgenology and the internist, 85; the value of, and benzene in the treatment of polycythemia vera, 782.

Roentgenological diagnosis of congenital pyloric stenosis, 304.

Roentgenology and the internist, 85.

Rosenfeld, Samuel S., observations on pyelitis, 448.

Rovsing's operation, new operation for colon stasis modified form, 259.

Royal College of Surgeons of England, primary examination for the fellowship of the, 1095.

S

Sacrum fracture dislocation of the rupture of the third, fourth and fifth left sacral roots, and compression of the same roots on the right and also of the second sacral root on both sides; with some observations on superficial and deep innervation, 668.

Salvarsan and methylene blue in treatment of malaria, 122; death from, 298; in acute infections, observations on the use of, 870; the testing of, 647; treatment of amebic dysentery by enemata of, 1140, of, 647.

Sanatoria, treatment of soldiers with cardiac affections in, 122.

Sandwith, Dr. Fleming Mant, death of, 603.

Sanitary code of New York State, amendments to, 339; conditions at Camp Greene, investigation of, 334; work in areas around military camps, 333.

Sanitation and the army surgeon, 154; in extra cantonment zones, 466; of the extra cantonment zones, 598.

Sarcoma of tonsil, radical operation, 439.

Scalp, dermatoses of the, 15.

Scarlatina in adult, relapse of, 346; on the complement fixation reaction in, and other exanthemata of childhood, 874.

Scarlet fever, etiology of, 1092; rapid cure of, 688; serotherapy of, 741.

Schell, J. Thompson, a preliminary report of the use of ozonized chlorinated oil of eucalyptus, 806.

Schereschewsky, J. W., methods of prevention and control of disease in war industries, 585.

Schlapp, M. G., theoretical considerations of mental deficiency, 441.

Schlapp, M. G., and Paulsen, A. E., report on 10,000 cases from the Clearing House for Mental Defectives, 269.

Sclerosis, multiple, the presence of spirochetes in a case of, 1102.

Scholtz, Moses, dermatoses of the scalp, 15.

School child, the healthy; Schenectady's system of keeping him healthy, 890; lunches, New York City ordinance providing for, 337; Red Cross, for cripples, 156.

Schoonmaker, Hubert, training the myocardium, 492.

Schufeldt, R. W., initial world war material at the Army Medical Museum, 179.

Sciatic nerve, resection of, eosinophilia of lymph nodes after, 346.

Sclerotic processes in liver and kidneys, relations of tuberculosis to, 246.

Scorbutus. See Scurvy.

Scurvy at the front, 122, 168; being produced by feeding pasteurized milk, the unsettled question as to, 105; in army, 333; in the Russian army, 519; sporadic, true and false, 1102.

Secor, William Lee, autosenitized foreign protein; claim of superiority for it as a subcutaneous or intravenous injection, 548.

Secretions, internal, a case of disturbance of, 788; internal, and pediatrics, 150.

Selection, theory of (Selektions hypotesen), 1057.

Self-purification of streams, 1044.

Senility, kidney function in, 342; nervous diseases of, 451.

Sepsis and antiseptics, 25; gastrointestinal, cause of Ménière's symptoms, 120; oral, streptococcus, 135.

Septicemia, pseudomalarial, cause unknown, with meningococcus meningitis, 121.

Sequestra in bone cavities, treatment of, 35.

Serology, recent consideration of, on meningococcus, 79.

Serum disease after intrathecal injections of serum, 31; therapy of partial tetanus, 112.

Service, a new call to, 644; combatant, liability of medical students for, 117.

Sexual inversion, the reversion of, by an exchange of the sexual glands, 781.

Sheffield, Herman B., select medication in children, 1078.

Shell shock cases, Smith College to train workers for, 1047; hospital treatment of, 726; treatment of neurasthenia and psychasthenia following, 32.

- Shock, certain views of, 914; a French view of, 729; primary causes of, 994; the primary cause of, additional experiments induced by the war, 927; recent literature on, 257; traumatic, 959; wound, intravenous injection in, 1101.
- Shoulders, observations on disabled, 605.
- Shufeldt, R. W., the teratological collection of the army medical museum, 620.
